Preface

Food biochemistry principles and knowledge have become indispensable in practically all the major disciplines of food science, such as food technology, food engineering, food biotechnology, food processing, and food safety within the past few decades. Knowledge in these areas has grown exponentially and keeps growing, and is disseminated through various media in both printed and electronic forms, and entire books are available for almost all the distinct specialty areas mentioned above. The two areas of food biochemistry and food processing are becoming closely interrelated. Fundamental knowledge in food biochemistry is crucial to enable food technologists and food processing engineers to rationalize and develop more effective strategies to produce and preserve food in safe and stable forms. Nonetheless, books combining food biochemistry and food processing/engineering principles are rare, and the first edition of this book was designed to fill the gap by assembling information on following six broad topics in the two areas:

1. Principles of food biochemistry.
2. Advances in selected areas of food biochemistry.
3. Food biochemistry and the processing of muscle foods and milk.
4. Food biochemistry and the processing of fruits, vegetables and cereals.
5. Food biochemistry and the processing of fermented foods.
6. Food microbiology and food safety.

These topics were spread over 31 chapters in the first edition.

The second edition of the book provides an update of several chapters from the first edition and expands the contents to encompass eight broad topics as follows:

1. Principles and analyses
2. Biotechnology and enzymology
3. Muscle foods (meats, poultry, and fish)
4. Milk and dairy

5. Fruits, vegetables, and cereals
6. Health and functional foods
7. Food processing
8. Food safety and food allergens

These eight broad topics are spread over 45 chapters in the second edition, and represents close to 50% increase in content over the previous version. In addition, abstracts capturing the salient features of the different chapters are provided in this new edition of the book.

The book is the result of the combined efforts of more than 65 professionals with diverse expertise and backgrounds in food biochemistry, food processing, and food safety who are affiliated with industry, government research institutions, and academia from over 18 countries. These experts were led by an international editorial team of six members from four countries in assembling together the different topics in food biochemistry, food commodities, food processing, and food safety in this one book.

The end product is unique, both in depth and breadth, and is highly recommended both as an essential reference book on food biochemistry and food processing for professionals in government, industry, and academia; and as classroom text for undergraduate courses in food chemistry, food biochemistry, food commodities, food safety, and food processing principles.

We wish to thank all the contributing authors for sharing their knowledge and expertise for their invaluable contribution and their patience for staying the course and seeing this project through.

Part 1
Principles/Food Analysis

1
An Introduction to Food Biochemistry

Rickey Y. Yada, Brian Bryksa, and Wai-kit Nip

Abstract: Compared to the siloed commodity departments of the past, the multi-disciplinary field of food science and technology has increasingly adopted a less segregated and more synergistic approach to research. At their most fundamental levels, all food-related processes from harvest to digestion are ways of bringing about, or preventing, biochemical changes. We contend that there is not a single scientific investigation of a food-related process that can avoid biochemical considerations. Even food scientists studying inorganic materials used in processing equipment and/or packaging must eventually consider potential reactions with biomolecules encountered in food systems. Moreover, since the food that we eat plays a central role in our overall well-being, it follows that tomorrow's food scientists and technologists must have a solid foundation in food biochemistry if they are to be innovators and visionaries. Introductions to biochemical topics are provided in this chapter, under the categories of carbohydrates, proteins, lipids, DNA, and toxicants. Within these broad divisions, general and specific food biochemical concepts are introduced, many of which are explored in detail in the chapters that follow.

INTRODUCTION

Many biochemical reactions and their products are the basis of much of food science and technology. Food scientists must be interdisciplinary in their approaches to studying and solving problems that require the integration of several disciplines, such as physics, chemistry, biology and various social sciences (e.g. sensory science, marketing, consumer attitude/acceptability). For example, in the development of food packaging materials, one must consider microbiological, environmental, biochemical (flavour/nutrient) and economic questions in addition to material/polymer science. In today's market, product development considerations may include several of the following: nutritional, environmental, microbiological (safety and probiotic), nutraceutical and religious/cultural questions in addition to cost/marketing and formulation methods. An ideal food product would promote healthy gut microflora, contain 20 g of vegetable

protein with no limiting amino acids and have 25% of the daily fibre requirement. It would be lactose-free, nut-free, trans-fat-free, antibiotic- and pesticide-free, artificial colour-free, no sugar added and contain certified levels of phytosterols. The product would contain tasteless, odourless, mercury-free, cold-pressed, bioactive omega 3-rich fish oil harvested using animal-friendly methods. Furthermore, it would be blood sugar-stabilising and heart disease-preventing, boost energy levels, not interfere with sleep, be packaged in minimal, compostable packaging and manufactured using 'green' energy, transported by biodiesel-burning trucks and be available to the masses at a reasonable price.

At their most fundamental levels, growing crops and raising food animals, storing or ageing foods, processing via fermentation, developing food products, preparing and/or cooking, and finally ingesting food are all ways of bringing about, or preventing, biochemical changes. Furthermore, methods to combat both pathogenic and spoilage organisms are based upon biochemical effects, including acidifying their environments, heat denaturing their membrane proteins, oxygen depriving, water depriving and/or biotin synthesis inhibiting. Only recently have the basic mechanisms behind food losses and food poisoning begun to be unravelled.

Food scientists recognised long ago the importance of a biochemistry background, demonstrated by the recommendation of a general biochemistry course requirement at the undergraduate level by the Institute of Food Technologists (IFT) in the United States more than 40 years ago. Many universities in various countries now offer a graduate course in food biochemistry as an elective or have food biochemistry as a specialised area of expertise in their undergraduate and graduate programs. The complexity of this area is very challenging; a content-specific journal, the Journal of Food Biochemistry, has been available since 1977 for scholars to report their food biochemistry-related research results.

Our greater understanding of food biochemistry has followed developments in food processing technology and biotechnology, resulting in improved nutrition and food safety. For example, milk-intolerant consumers can ingest nutritious dairy products that are either lactose-free or by taking pills that contain an enzyme to reduce or eliminate lactose. People can decrease gas production resulting from eating healthy legumes by taking α-galactosidase (produced by *Aspergillus niger*) supplements with meals. Shark meat is made more palatable by controlling the action of urease on urea. Tomato juice production is improved by proper control of its pectic enzymes. Better colour in potato chips results from removal of sugars from the cut potato slices. More tender beef results from proper aging of carcasses or at the consumer level, the addition of instant marinades containing protease(s). Ripening inhibition of bananas during transport is achieved by controlling levels of the ripening hormone, ethylene, in packaging. Proper chilling of caught tuna minimises histamine production by inhibiting the activities of certain bacteria, thereby avoiding scombroid or histamine poisoning. Beyond modified atmosphere packaging, 'intelligent' packaging materials that respond to and delay certain deteriorative biochemical reactions are being developed and utilised. The above are just a few of the examples that will be discussed in more detail in this chapter and in the commodity chapters in this book.

The goal of this introductory chapter is to provide the reader with an overview of both basic and applied biochemistry as they relate to food science and technology, and to act as a segue into the following chapters. Readers are strongly encouraged to consult the references provided for further detailed information.

BIOCHEMISTRY OF FOOD CARBOHYDRATES

'Carbohydrate' literally means 'carbon hydrate,' which is reflected in the basic building block unit of simple carbohydrates, i.e. $(CH_2O)_n$. Carbohydrates make up the majority of organic mass on earth having the biologically important roles of energy storage (e.g. plant starch, animal glycogen), energy transmission (e.g. ATP, many metabolic intermediates), structural components (e.g. plant cellulose, arthropod chitin), and intra- and extracellular communication (e.g. egg-sperm binding, immune system recognition). Critical for the food industry, carbohydrates serve as the primary nutritive energy sources from foods like grains, fruits and vegetables, as well as being important ingredients for many formulated or processed foods. Carbohydrates are used to sweeten, gel, emulsify, encapsulate or bind flavours, can be altered to produce colour and flavour via various browning reactions, and are used to control humidity and water activity.

STRUCTURES

The basic unit of a carbohydrate is a monosaccharide; 2 monosaccharides bound together are called a disaccharide; 3 are called a trisaccharide, 2–10 monosaccharides in a chain are termed an oligosaccharide, and 10 or more are termed a polysaccharide. The simplest food-related carbohydrates, monosaccharides, are glucose, mannose, galactose and fructose.

Carbohydrate structures contain several hydroxyl groups (–OH) per molecule, a structural feature that imparts a high capacity for hydrogen bonding, making them very hydrophilic. This property allows them to serve as a means of moisture control in foods. The ability of a substance to bind water is termed humectancy, one of the most important properties of carbohydrates in foods. Maltose and lactose (discussed later) have relatively low humectancies; therefore, they allow for sweetness while resisting adsorption of environmental moisture. Hygroscopic (water absorbing) sugars like corn syrup and invert sugar (hydrolysed table sugar) help prevent water loss, e.g. in baked goods. In addition to the presence of hydroxyl groups, humectancy is also dependent on the overall structures of carbohydrates, e.g. fructose binds more water than glucose.

SUGAR DERIVATIVES – GLYCOSIDES

Most chemical reactions of carbohydrates occur via their hydroxyl and carbonyl groups. Under acidic conditions, the carbonyl carbon of a sugar can react with the hydroxyl of an alcohol, e.g. methanol (wood alcohol) to form *O-glycosidic bonds*. Other examples of glycosidic bonds are those between sugar carbonyl groups and amines (e.g. some amino acids as well as molecules such as DNA and RNA building blocks), as well as sugar carbonyl bonding with phosphate (e.g. phosphorylated

metabolic intermediates). A glycosidic bond between a carbonyl carbon and the nitrogen of an amine group (R–NH) is termed an *N-glycosidic bond*. Similarly, reactions of carbonyl carbons with thiols (R–SH) produce *thio-glycosides*.

FOOD DISACCHARIDES

The food carbohydrates sucrose, lactose and maltose (see structures below) are disaccharides (two monosaccharides joined by an *O*-glycosydic bond) and are three of the principal disaccharides used in the food industry. Used as a sweetening agent and fermentation carbon source, sucrose exists naturally in high amounts only in cane and beet, is composed of one glucose and one fructose and is a *non-reducing sugar* since it contains no free aldehyde. The enzymes responsible for catalysing the hydrolysis of sucrose to glucose and fructose are sucrases and invertases, which catalyse the hydrolysis of the sucrose glycosidic bond. Acid and heat also cause hydrolysis of sucrose, which is important in the commercial production of invert sugar, where sucrose is partially converted to glucose and fructose, thereby producing increased sweetness and water-binding ability.

The disaccharide lactose is made up of galactose and glucose, and is often referred to as milk sugar. Lactose is hydrolysed by lactase (EC 3.2.1.108), an enzyme of the β-galactosidase enzyme class, produced by various mammals, bacteria and fungi. By adulthood, some humans produce insufficient amounts of lactase, thereby restricting the consumption of dairy product in significant quantities. In deficient persons, a failure to hydrolyse lactose in the upper intestine results in this simple sugar passing into the large intestine, which in turn results in an influx of water as well as fermentation by lower gut bacteria, leading to bloating, cramping and diarrhoea. Lactose levels in dairy products can be reduced by treatment with lactase or by lactic acid bacteria fermentation. 'Lactose-free' milk products are widely sold and marketed with most of the lactose hydrolysed by treatment with lactase. Also, fermented dairy foods like yoghurt and cheese contain less lactose compared to the starting materials where the lactose is converted into lactic acid by bacteria, e.g. old cheddar cheese contains virtually no remaining lactose.

Maltose is composed of two glucose units and is derived from starch by treatment with β-amylase, thereby increasing the sweetness of the reaction mixture. The term *malt* (beer making) refers to the product where β-amylase, produced during the germination, has acted on the starch of barley or other grains when steeped in water.

CARBOHYDRATE BROWNING REACTIONS

There are three general categories of browning reactions in foods: oxidative/enzymatic browning, *caramelisation* and non-oxidative/non-enzymatic/*Maillard browning*. Oxidative browning is discussed later in the section on proteins. The latter two types of browning involve carbohydrate reactions. Caramelisation involves a complex group of reactions that are the result of direct heating of carbohydrates, particularly sugars. Dehydration reactions result in the formation of double bonds along with the polymerisation of ring structures that absorb different light wavelengths, hence the flavour development, darkening

and colour formation in such mixtures. Two important roles of caramelisation in the food industry are caramel flavour and colour production, a processes in which sucrose is heated in solution with acid or acid ammonium salts to produce a variety of products in food, candies and beverages (Ko et al. 2006).

The Maillard reaction is one of the most important reactions encountered in food systems, and it is also called non-enzymatic or non-oxidative browning. Reducing sugars and amino acids or other nitrogen-containing compounds react to produce *N*-glycosides displaying red-brown to very dark brown colours, caramel-like aromas, and colloidal and insoluble melanoidins. There are a complex array of possible reactions that can take place via Maillard chemistry, and the aromas, flavours and colours can be desirable or undesirable (BeMiller and Whistler 1996). Lysine is a nutritionally essential amino acid and its side chain can react during the Maillard reaction, thereby lowering the nutritional value of foods. Other amino acids that may be lost due to the Maillard reaction include the basic amino acids L-arginine and L-histidine.

STARCH

Polysaccharides, or glycans, are made up of glycosyl units in a linear or branched structure. The three major food-related glycans are amylose, amylopectin and cellulose (cellulose is discussed below), which are all chains of D-glucose, but are structurally distinct based on the types of glycosidic linkages that join the glucose units and the amount of branching in their respective structures. Both amylose and amylopectin are components of starch, the energy storage molecules of plants, and cellulose is the structural carbohydrate that provides structural rigidity to plants. Starch is a critical nutritional component of many foods, especially flour-based foods, tubers, cereal grains, corn and rice. Starch can be both linear (amylose) and branched (amylopectin). Amylose glucose units are joined only by α-1,4-linkages and it usually contains 200–3000 units. Amylopectin also contains α-1,4-linkages, but additionally it has branch points at α-1,6 linkages that occur approximately every 20–30 α-linkages. The branched molecules of amylopectin produce bulkier structures than amylose. Most starches contain approximately 25% amylose, although amylose contents as high as 85% are possible. Starches containing only amylopectin are termed waxy starches.

Starch exists in *granules* that are deposited in organelles called amyloplasts. Granule size and shape vary with plant source, and they contain a cleft called the hilium, which serves as a nucleation point around which the granule develops as part of plant energy storage. Granules vary in size from 2 to 130 μ and they have a crystalline structure such that the starch molecules align radially within the crystals.

METABOLISM OF CARBOHYDRATES

The characteristics of carbohydrates in both their natural states and as processed food ingredients determine the properties of many foods as well as their utilisation as nutrients. *Glycolysis* is a fundamental pathway of metabolism consisting of a series of reactions in the cytosol, where glucose is converted to pyruvate via nine enzymatically catalysed reactions (see Figure 1.1).

Glucose
Glucose 6-P
Fructose 6-P
Fructose 1,6-Bis-P
Glyceraldehyde 3-P ⇌ Dihydroxyacetone-P
1,3-Bis-phosphoglycerate
3-Phosphoglycerate
2-Phosphoglycerate
Phosphoenolpyruvate
Pyruvate ⇌ Lactate

If aerobic   *If anaerobic*

[TCA cycle]
Figure 1.1. Outline of glycolysis; 3-C reactions beginning with glyceraldehyde 3-P occur twice per glucose.

Glycolytic processing of each glucose molecule results in a modest gain of only two ATPs (the universal biochemical energy currency). Although the gain of two ATPs is small, the creation of pyruvate feeds another metabolic pathway, the tricarboxylic acid (TCA) cycle, which yields two more ATPs. More importantly, glycolysis and the TCA cycle also generate the reduced forms of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$), which drive subsequent oxidative phosphorylation of ADP. An overview of the TCA cycle is depicted in Figure 1.2. NADH and $FADH_2$ generated by glycolysis and the TCA cycle are subsequently part of oxidative phosphorylation, where they transfer their electrons to O_2 in a series of electron transfer reactions whose high energy potential is used to drive phosphorylation. Overall, a net yield of 30 ATPs is gained per glucose molecule as the result of glycolysis, the TCA cycle and oxidative phosphorylation.

Pyruvate (from glycolysis)

Citrate   Isocitrate
Oxaloacetate
Malate   α-Ketoglutarate
Fumarate   Succinyl CoA
        Succinate
Figure 1.2. An overview of the TCA cycle.

Intermediates of carbohydrate metabolism play an important role in many food products. The conversion products of glycogen in fish and mammalian muscles are now known to utilise different pathways, but ultimately result in glucose-6-phosphate, leading into glycolysis. Lactic acid formation is an important phenomenon in rigor mortis, and souring and curdling of milk as well as in manufacturing sauerkraut and other fermented vegetables. Ethanol is an important end product in the production of alcoholic beverages, bread making and in some overripe fruits to a lesser extent. The TCA cycle is also important in alcoholic fermentation, cheese maturation and fruit ripening. In bread making, α-amylase (added or present in the flour itself) partially hydrolyses starch to release glucose units as an energy source for yeast growth and development, which is important for the dough to rise during fermentation.

During germination of cereal grains, glucose and glucose phosphates or fructose phosphates are produced from starch. Some of the relevant biochemical reactions are summarised in Table 1.1. The sugar phosphates are then converted to pyruvate via glycolysis, which is utilised in various biochemical reactions. The glucose and sugar phosphates can also be used in the building of various plant structures, e.g. cellulose is a glucose polymer and is the major structural component of plants.

In addition to starch, plants also possess complex carbohydrates, e.g. cellulose, β-g1ucans and pectins. Both cellulose and β-glucans are composed of glucose units bound by β-g1ycosidic linkages that cannot be metabolised in the human body. They are important carbohydrate reserves in plants that can be metabolised into smaller molecules for utilisation during seed germination. Pectic substances (pectins) act as the "glue" among cells in plant tissue and also are not metabolised in the human body. Together with cellulose and β-g1ucans, pectins are classified as dietary fibre.

Derivatives of cellulose can be made through chemical modification under strongly basic conditions where side chains such as methyl and propylene react and bind at sugar hydroxyl groups. The resultant derivatives are ethers (oxygen bridges) joining sugar residues and the side chain groups (Coffee et al. 1995). A major function of cellulose derivatives is to act as a bulking agent in food products. Two examples of important food-related derivatives of cellulose are carboxymethylcellulose and methylcellulose.

Pectin substances include polymers composed mainly of α-(1,4)-D-galacturonopyranosyl units and constitute the middle lamella of plant cells. Pectins exist in the propectin form in unripe (green) fruit, contributing to firm, hard structures. Upon ripening, propectins are metabolised into smaller molecules, giving ripe fruits a soft texture. Controlling enzymatic activity against propectin is commercially important in fruits such as tomatoes, apples and persimmons. Research and the development of genetically modified tomatoes allowed uniform ripening prior to processing and consumption. Fuji apples can be kept in the refrigerator for a much longer time than other varieties of apples before reaching the soft, grainy texture stage due to a lower pectic enzyme activity. Persimmons are hard in the unripe stage, but can be ripened to a very soft texture as a result of pectic- and starch-degrading enzymes. Table 1.2

Table 1.1. Starch Degradation During Cereal Grain Germination

Enzyme	Reaction
α-Amylase (EC 3.2.1.1)	Starch $\rightarrow$ Glucose + Maltose + Maltotriose + α-Limit dextrins + Linear maltosaccharides
Hexokinase (EC 2.7.1.1)	Glucose + ATP $\rightarrow$ Glucose-6-phosphate + ADP
α-Glucosidase (maltase, EC 3.2.1.20)	Hydrolysis of terminal, non-reducing 1,4-linked α-D-glucose residues releasing α-D-glucose
Oligo-1,6 glucosidase (limit dextrinase, isomaltase, EC 3.2.1.10)	α-Limit dextrin $\rightarrow$ Linear maltosaccharides
β-Amylase (EC 3.2.1.2)	Linear maltosaccharides $\rightarrow$ Maltose
Phosphorylase (EC 2.4.1.1)	Linear maltosaccharides + Phosphate $\rightarrow$ α-D-Glucose-1-phosphate
Phosphoglucomutase (EC 5.4.2.2)	α-D-Glucose-1-phosphaate $\rightarrow$ α-D-Glucose-6-phosphate
Glucosephosphate isomerase (EC 5.3.1.9)	D-Glucose-6-phosphate $\rightarrow$ D-Fructose-6-phosphate
UTP-glucose-1-phosphate uridyl transferase (UDP-glucose pyrophosphorylase, EC 2.7.7.9)	UTP + α-D-Glucose-1-phosphate $\rightarrow$ UDP-glucose + Pyrophosphate
Sucrose phosphate synthetase (EC 2.4.1.14)	UDP-glucose + D-Fructose-6-phosphate $\rightarrow$ Sucrose phosphate + UDP
Sugar phosphate phosphohydrolase (sugar phosphatase, EC 3.1.3.23)	Sugar phosphate (fructose-6-phosphate) $\rightarrow$ Sugar (fructose) + Inorganic phosphate
Sucrose phosphatase (EC 3.1.3.24)	Sucrose-6-F-phosphate $\rightarrow$ Sucrose + Inorganic phosphate
Sucrose synthetase (EC2.4.1.13)	NDP-glucose + D-Fructose $\rightarrow$ Sucrose + NDP
β-Fructose-furanosidase (invertase, saccharase, EC 3.2.1.26)	Sucrose $\rightarrow$ Glucose + Fructose

Table 1.2. Degradation of Complex Carbohydrates

Enzyme	Reaction
Cellulose degradation during seed germination[a]	
Cellulase (EC 3.2.1.4)	Endohydrolysis of 1,4-β-glucosidic linkages in cellulose and cereal β-D-glucans
Glucan 1,4-β-glucosidase (exo-1,4, β-glucosidase, EC 3.2.1.74)	Hydrolysis of 1,4 linkages in 1,4-β-D-glucan so as to remove successive glucose units
Cellulose 1,4-β-cellubiosidase (EC 3.2.1.91)	Hydrolysis of 1,4-β-D-glucosidic linkages in cellulose and cellotetraose releasing cellubiose from the non-reducing ends of the chains
β-Galactosan degradation[a]	
β-Galactosidase (EC 3.21.1.23)	β-(1$\rightarrow$4)-linked galactan $\rightarrow$ D-Galactose
β-Glucan degradation[b]	
Glucan endo-1,6, β-glucosidase (EC 3.2.1.75)	Random hydrolysis of 1,6 linkages in 1,6-β-D-glucans
Glucan endo-1,4, β-glucosidase (EC 3.2.1.74)	Hydrolysis of 1,4 linkages in 1,4-β-D-glucans so as to remove successive glucose units
Glucan endo-1,3-β-D-glucanase (EC 3.2.1.58)	Successive hydrolysis of β-D-glucose units from the non-reducing ends of 1,3-β-D-glucans, releasing α-glucose
Glucan 1,3-β-glucosidase (EC 3.2.1.39)	1,3-β-D-glucans $\rightarrow$ α-D-glucose
Pectin degradation[b]	
Polygalacturonase (EC 3.2.1.15)	Random hydrolysis of 1,4-α-D-galactosiduronic linkages in pectate and other galacturonans
Galacturan 1,4-α-galacturonidase (EC 3.2.1.67)	(1,4-α-D-Galacturoniside)$_n$ + H_2O $\rightarrow$ (1,4-α-D-Galacturoniside)$_{n-1}$ + D-Galacturonate
Pectate lyase (pectate transeliminase, EC 4.2.2.2)	Eliminative cleavage of pectate to give oligosaccharides with 4-deoxy-α-D-galact-4-enuronosyl groups at their non-reducing ends
Pectin lyase (EC 4.2.2.10)	Eliminative cleavage of pectin to give oligosaccharides with terminal 4-deoxy-6-methyl-α-D-galact-4-enduronosyl groups

Table 1.3. Changes in Carbohydrates in Cheese Manufacturing

Action, Enzyme or Enzyme System	Reaction
Formation of lactic acid	
Lactase (EC 3.2.1.108)	Lactose + $H_2O \rightarrow$ D-Glucose + D-Galactose
Tagatose pathway	Galactose-6-P $\rightarrow$ Lactic acid
Embden–Meyerhoff pathway	Glucose $\rightarrow$ Pyruvate $\rightarrow$ Lactic acid
Formation of pyruvate from citric acid	
Citrate (*pro-3S*) lyase (EC 4.1.3.6)	Citrate $\rightarrow$ Oxaloacetate
Oxaloacetate decarboxylase (EC 4.1.1.3)	Oxaloacetate $\rightarrow$ Pyruvate + CO_2
Formation of propionic and acetic acids	
Propionate pathway	3 Lactate $\rightarrow$ 2 Propionate + 1 Acetate + CO_2 + H_2O
	3 Alanine $\rightarrow$ Propionic acid + 1 Acetate + CO_2 + 3 Ammonia
Formation of succinic acid	
Mixed acid pathway	Propionic acid + CO_2 $\rightarrow$ Succinic acid
Formation of butyric acid	
Butyric acid pathway	2 Lactate $\rightarrow$ 1 Butyrate + CO_2 + $2H_2$
Formation of ethanol	
Phosphoketolase pathway	Glucose $\rightarrow$ Acetylaldehyde $\rightarrow$ Ethanol
Pyruvate decarboxylase (EC 4.1.1.1)	Pyruvate $\rightarrow$ Acetylaldehyde + CO_2
Alcohol dehydrogenase (EC 1.1.1.1)	Acetylaldehyde + NAD + H^+ $\rightarrow$ Ethanol + NAD^+
Formation of formic acid	
Pyruvate-formate lyase (EC 2.3.1.54)	Pyruvate + CoA $\rightarrow$ Formic acid + Acetyl CoA
Formation of diacetyl, acetoin, 2,3-butylene glycol	
Citrate fermentation pathway	Citrate $\rightarrow$ Pyruvate $\rightarrow$ Acetyl CoA $\rightarrow$ Diacetyl $\rightarrow$ Acetoine $\rightarrow$ 2,3-Butylene glycol
Formation of acetic acid	
Pyruvate-formate lyase (EC 2.3.1.54)	Pyruvate + CoA $\rightarrow$ Formic acid + Acetyl CoA
Acetyl-CoA hydrolase (EC 3.1.2.1)	Acetyl CoA + $H_2O \rightarrow$ Acetic acid + CoA

lists some of the enzymes and their reactions related to these complex carbohydrates.

METABOLISM OF LACTOSE IN CHEESE PRODUCTION

Milk does not contain high-molecular weight carbohydrates; however, it does contain lactose. Lactose can be enzymatically degraded to glucose and galactose-6-phosphate by the enzyme lactase, which can be produced by lactic acid bacteria. Glucose and galactose-6-phosphate are then further metabolised to various smaller molecules through various biochemical reactions that are important in the flavour development of various cheeses, e.g. butyric acid via lactic acid decarboxylation. Table 1.3 lists some of these enzymatic reactions.

REMOVAL OF GLUCOSE IN EGG POWDER

Glucose is present in very small quantities in egg albumen and egg yolk; however, it can undergo non-enzymatic reactions, e.g. Maillard reactions, which lower the quality of the final products. This problem can be overcome by using the glucose oxidase–catalase system. Glucose oxidase converts glucose to gluconic acid and hydrogen peroxide, which then decomposes into water and oxygen by the action of catalase. This process is used almost exclusively for whole egg and other yolk-containing products. However, for dehydrated egg albumen, bacterial and/or yeast fermentation is used to remove glucose.

PRODUCTION OF STARCH SUGARS AND SYRUPS

The hydrolysis of starch by means of enzymes (α- and β-amylases) and/or acid to produce glucose (dextrose, D-glucose) and maltose syrups has resulted in the availability of various starch syrups, maltodextrins, maltose and glucose for the food, pharmaceutical and other industries. In the 1950s, researchers discovered that some xylose isomerase (D-xylose-keto-isomerase, EC 5.3.1.5) preparations possessed the ability to convert D-glucose to D-fructose. In the early 1970s, researchers developed immobilised enzyme technology for various applications. Since fructose is sweeter than glucose, xylose isomerase was successfully applied to this new technology with the production of high-fructose syrup (called high-fructose corn syrup in the United States; Carasik and Carroll 1983). High-fructose syrups have since replaced most of the glucose syrups in the soft drink industry.

FOOD PROTEIN BIOCHEMISTRY

PROPERTIES OF AMINO ACIDS

Proteins are polymers of *amino acids* joined by *peptide bonds*. Twenty amino acids commonly exist and their possible combinations result in the potential for an incredibly large number of sequence and 3D structural protein variants. Amino acids consist of a carbon atom (C_α) that is covalently bonded to an amino group and a carboxylic acid group. Thus, they have an $N–C_\alpha–C$ 'backbone'. In addition, the C_α is bound to a hydrogen atom and one of 20 'R groups' or 'side chains', hence the general formula:

$$+ NH_3 − CHR − COO^-$$

The above general formula describes 19 of the 20 amino acids except proline, whose side chain is irregular, in that it is covalently bound to both the α-carbon and the backbone nitrogen. The covalent bonds among different amino acids in a protein are called peptide bonds. The 20 amino acids can be divided into three categories based on R-group differences: non-polar, polar and charged polar. The functional properties of food proteins are directly attributable to the amino acid R-group properties: structural (size, shape and flexibility), ionic (charge and acid–base character) and polarity (hydrophobicity/hydrophilicity).

At neutral pH, most free amino acids are zwitterionic, i.e. they are dipolar ions, carrying both a positive and negative charge, as shown in the general formula above. Since the primary amino and carboxyl groups of amino acids are involved in peptide bonds within a protein, it is only the R groups (and the ends of the peptide chains) that contribute to charge; the charge of a protein being determined by the charge states of the ionisable amino acid R groups that make up the polypeptide, namely aspartic acid (Asp), glutamic acid (Glu), histidine (His), lysine (Lys), arginine (Arg), cysteine (Cys) and tyrosine (Tyr). The acidic amino acids are Tyr, Cys, Asp and Glu (note: Tyr and Cys require pH above physiologic pH to act as acids, and therefore, are less important charge contributors in living systems). Lys, Arg and His are basic amino acids.

The amino acid sequence and properties determine overall protein structure. Some examples are as follows: Two residues of opposite charges can form a salt bridge. For example, Lys and Asp typically have opposite charges under the same conditions, and if the side chains are proximate, then the negatively charged carboxylate of Asp can salt-bridge to the positively charged ammonium of Lys. Another important inter-residue interaction is covalent bonding between Cys side chains. Under oxidising conditions, the sulfhydryl groups of Cys side chains (–S–H) can form a thiol covalent bond (–S–S–) also known as a *disulphide bond*. Lastly, hydrophobic (non-polar) amino acids are generally sequestered away from the solvent in aqueous solutions (which is not always the case for food products), since interaction with polar molecules is not energetically stable.

PROTEIN NUTRITIONAL CONSIDERATIONS

In terms of survival and good health, the contributions of protein in the diet are to provide adequate levels of what are referred to as 'essential amino acids' (Lys, methionine, phenylalanine, threonine, tryptophan, valine, leucine and isoleucine), amino acids that are either not produced in sufficient quantities or not at all by the body to support building/repairing and maintaining tissues as well as protein synthesis. Single source plant proteins are referred to as incomplete proteins since they do not have sufficient quantities of the essential amino acids in contrast to animal proteins, which are complete. For example, cereals are deficient in Lys, while oilseeds and nuts are deficient in Lys as well as methionine. In order for plant proteins to become 'complete', complementary sources of proteins must be consumed, i.e. the deficiency of one source is complemented by an excess from another source, thus making the combined protein 'complete'.

Although some amino acids are *gluconeogenic*, meaning that they can be converted to glucose, proteins are not a critical source of energy. Dietary protein breakdown begins with cooking (heat energy) and chewing (mechanical energy) followed by acid treatment in the stomach (chemical energy) as well as the mechanical actions of the upper GI. The 3D structures of proteins are partially lost due to such forces and are said to 'unfold' or denature.

In addition to protein denaturation, the stomach and upper intestine produce two types of *proteases* (enzymes that hydrolyse peptide bonds) that act on dietary proteins. *Endopeptidases* are proteases that cleave interior peptide bonds of polypeptide chains, while *exopeptidases* are proteases that cleave at the ends of proteins exclusively. Pepsin, an acid protease that functions optimally at extremely low pH of the stomach, releases peptides from muscle and collagen proteins. In the upper intestine, serine proteases trypsin and chymotrypsin further digest peptides, yielding free amino acids for absorption into the blood (Champe et al. 2005). An important consideration regarding the nutritional quality of proteins is the effect of processing. Heat and chemical treatments can serve to unfold proteins, thereby aiding to increase enzymatic hydrolysis, i.e. unfolded proteins have a larger surface area for enzymes to act. This may increase the amino acid bioavailability, but it can also lead to degradative/transformative reactions of amino acids, e.g. deamidation of asparagine and glutamine, reducing these amino acids as nutrient sources.

ANIMAL PROTEIN STRUCTURE AND PROTEOLYSIS IN FOOD SYSTEMS

Animal tissues have similar structures despite minor differences between land and aquatic (fish and shellfish) animal tissues. Post-mortem, meat structure breaks down slowly, resulting in desirable tenderisation and eventual undesirable degradation/spoilage. Understanding meat structure is critical to understanding these processes, and Table 1.4 lists the location and major functions of myofibrillar proteins associated with the contractile apparatus and cytoskeletal framework of animal tissues. Individual muscle fibres are composed of myofibrils, which are the basic units of muscular contraction. The skeletal muscle of fish differs from that of mammals, in that the fibres arranged between the sheets of connective tissue are much shorter. The connective tissue appears as short, transverse sheets

Table 1.4. Locations and Major Functions of Myofibrillar Proteins Associated with Contractile Apparatus and Cytoskeletal Framework

Location	Protein	Major Function
Contractile apparatus		
A-band	Myosin	Muscle contraction
	c-Protein	Binds myosin filaments
	F-, H-, I-Proteins	Binds myosin filaments
M-line	M-Protein	Binds myosin filaments
	Myomesin	Binds myosin filaments
	Creatine kinase	ATP synthesis
I-band	Actin	Muscle contraction
	Tropomyosin	Regulates muscle contraction
	Troponins T, I, C	Regulates muscle contraction
	β-, γ-Actinins	Regulates actin filaments
Cytoskeletal framework		
GAP filaments	Connectin (titin)	Links myosin filaments to Z-line
N_2-line	Nebulin	Unknown
By sarcolemma	Vinculin	Links myofibrils to sarcolemma
Z-line	α-Actinin	Links actin filaments to Z-line
	Eu-actinin, filamin	Links actin filaments to Z-line
	Desmin, vimmentin	Peripheral structure to Z-line
	Synemin, Z-protein, Z-nin	Lattice structure of Z-line

Source: Eskin 1990, Lowrie 1992, Huff-Lonergar and Lonergan 1999, Greaser 2001.

(myocommata) that divide the long fish muscles into segments (myotomes) corresponding in numbers to those of the vertebrae. A fine network of tubules, the sarcoplasmic reticulum, separates the individual myofibrils, and within each fibre is a liquid matrix referred to as the sarcoplasm-containing enzymes, mitochondria (cellular powerhouse), glycogen (carbohydrate storage form in animals), adenosine triphosphate (energy currency), creatine (part of energy transfer in muscle) and myoglobin (oxygen transport molecule). The basic unit of the myofibril is the sarcomere, which is made up of a thick set of filaments consisting mainly of myosin, a thin set containing primarily of F-actin and a filamentous 'cytoskeletal structure' composed of connectin and desmin. Meat tenderisation is a very complex, multi-factorial process involving glycolysis and the actions of both endogenous proteases (e.g. cathepsins and calpains) as well as intentionally added enzymes. Table 1.5 lists some of the more common enzymes used in meat tenderisation. Papain, ficin and bromelain are proteases of plant origin that efficiently break down animal proteins applied in meat tenderisation industrially or at the household/restaurant levels. Enzymes such as pepsins, trypsins and cathepsins cleave animal tissues at various sites of peptide chains, while enteropeptidase (enterokinase) is also known to activate trypsinogen by cleaving its Lys6-Ile7 peptide bond. Plasmin, pancreatic elastase and collagenase are responsible for the breakdown of animal connective tissues.

Chymosin (rennin) is the primary protease critical for the initial milk clotting step in cheese making and is traditionally obtained from calf stomach. Lactic acid bacteria (starter) gradually acidify milk to the pH 4.7, the optimal pH for coagulation by chymosin. Most lactic acid starters have limited proteolytic activities, i.e. product proteins are not degraded fully as in the case of GI tract breakdown of dietary proteins. The proteases and peptidases breakdown milk caseins to smaller protein molecules that, combined with milk fat, provide the cheese structure. Other enzymes such as decarboxylases, deaminases and transaminases are responsible for the degradation of amino acids into secondary amines, indole, α-keto acids and other compounds that give the typical flavour of cheeses (see Table 1.6 for enzymes and their reactions).

Germinating seeds also undergo proteolysis, although in a much lower amount relative to meat. Aminopeptidase and carboxypeptidase A are the main, known enzymes (Table 1.7) here that produce peptides and amino acids needed in the growth of the plant.

In beer production, a small amount of protein is dissolved from the wheat and malt into the wort. The protein fraction extracted from the wort may precipitate if present in the resulting beer due to its limited solubility at lower temperatures, resulting in hazing. Proteases of plant origin such as papain, ficin and bromelain break down such proteins to reduce this 'chill-haze' problem in the brewing industry.

PROTEIN MODIFICATIONS

A protein's amino acid sequence is critical to its physico-chemical properties, and it follows that changes made to individual amino acids may alter its functionality. In addition to the many chemical alterations that may occur to amino acids during

Table 1.5. Proteases in Animal Tissues and Their Degradation

Enzyme	Reaction
Aspartic proteases	
Pepsin A (pepsin, EC 3.4.23.1)	Preferential cleavage, hydrophobic, preferably aromatic, residues in P1 and P'1 positions
Gastricsin (pepsin C, EC 3.4.23.3)	More restricted specificity than pepsin A; high preferential cleavage at Tyr bond
Cathepsin D (EC 3.4.23.5)	Specificity similar to, but narrower than that of pepsin A
Serine proteases	
Trypsin (a- and b-trypsin, EC 3.4.21.4)	Cleavage to the C-terminus of Arg and Lys
Chymotrypsin (Chymotrypsin A and B, EC 3.4.21.1)	Preferential cleavage: Tyr-, Trp-, Phe-, Leu-
Chymotrysin C (EC 3.4.21.2)	Preferential cleavage: Leu-, Tyr-, Phe-, Met-, Trp-, Gln-, Asn-
Pancreatic elastase (pancreato-peptidase E, pancreatic elastase I, EC 3.4.21.36)	Hydrolysis of proteins, including elastin. Preferential cleavage: Ala
Plasmin (fibrinase, fibrinolysin, EC 3.4.21.7)	Preferential cleavage: Lys >Arg; higher selectivity than trypsin
Enteropeptidase (enterokinase, EC 3.4.21.9)	Activation of trypsinogen by selective cleavage of Lys6-Ile7 bond
Collagenase	Hydrolysis of collagen into smaller molecules
Thio/cysteine proteases	
Cathepsin B (cathepsin B1, EC 3.4.22.1)	Broad speicificity, Arg–Arg bond preference in small peptides
Papain (EC 3.4.22.2)	Broad specificity; preference for large, hydrophobic amino acid at P2; does not accept Val at P1′
Fiacin (ficin, EC 3.4.23.3)	Similar to that of papain
Bromelain (EC 3.4.22.4)	Broad specificity similar to that of pepsin A
γ-Glutamyl hydrolase (EC 3.4.22.12 changed to 3.4.1.99)	Hydrolyses γ-glutamyl bonds
Cathepsin H (EC 3.4.22.16)	Protein hydorlysis; acts also as an aminopeptidase and endopeptidase (notably cleaving Arg bond)
Calpain-1 (EC 3.4.22.17 changed to 3.4.22.50)	Limited cleavage of tropinin I, tropomyosin, myofibril C-protein, cytoskeletal proteins; activates phosphorylase, kinase, and cyclic-nucleotide-dependent protein kinase
Metalloproteases	
Procollagen N-proteinase (EC 3.4.24.14)	Cleaves N-propeptide of pro-collagen chain $\alpha1$(I) at Pro+Gln and $\alpha1$(II), and $\alpha2$(I) at Ala+Gln

Source: Eskin 1990, Haard 1990, Lowrie 1992, Huff-Lonergan and Lonergan 1999, Gopakumar 2000, Jiang 2000, Simpson 2000, Greaser 2001, IUBMB-NC website (www.iubmb.org).

food processing, e.g. deamidation, natural, enzymatic protein modifications collectively known as *post-translational modifications* may also occur upon their expression in cells. Some examples are listed in Table 1.8.

PROTEIN STRUCTURE

Protein folding largely occurs as a means to minimise the energy of the system where hydrophobic groups are maximally shielded from aqueous environments and while the exposure of hydrophilic groups to aqueous environments is maximised. Protein structures follow a hierarchy: primary, secondary, tertiary and quaternary structures. Primary structure refers to the amino acid sequence; secondary structures are the structures formed by amino acid sequences (e.g. α-helix, β-sheet, random coil); tertiary structures are the 3D structures made up of secondary structures (the way that helices, sheets and random coils

pack together) and quaternary structure refers to the association of tertiary structures (e.g. two subunits of an enzyme) in oligomeric proteins. The overall shapes of proteins fall into two general types: globular and fibrous. Enzymes, transport proteins and receptor proteins are examples of globular proteins having a compact, spherical shape. Hair keratin and muscle myosin are examples of fibrous proteins having elongated structures that are simple compared to globular proteins.

OXIDATIVE BROWNING

Oxidative browning, also called enzymatic browning, involves the actions of a group of enzymes generally referred to as polyphenol oxidase (PPO) or phenolase. PPO is normally compartmentalised in tissue such that oxygen is unavailable. Injury or cutting of plant material, especially apples, bananas, pears and lettuce, results in decompartmentalisation, making O_2 available

Table 1.6. Proteolytic Changes in Cheese Manufacturing

Enzyme	Reaction
Coagulation	
Chymosin (rennin, EC 3.4.23.4)	κ-Casein $\rightarrow$ Para-κ-casein + Glycopeptide, similar to pepsin A
Proteolysis	
Proteases	Proteins $\rightarrow$ High-molecular-weight peptides + Amino Acids
Amino peptidases, dipeptidases, tripeptidases	Low molecular weight peptides $\rightarrow$ Amino acids
Proteases, endopeptidases, aminopeptidases	High-molecular weight peptides $\rightarrow$ Low molecular weight peptides
Decomposition of amino acids	
Aspartate transaminase (EC 2.6.1.1)	L-Asparate + 2-Oxoglutarate $\rightarrow$ Oxaloacetate + L-Glutamate
Methionine γ-lyase (EC 4.4.1.11)	L-Methionine $\rightarrow$ Methanethiol + NH_3 + 2-Oxobutanolate
Tryptophanase (EC 4.1.99.1)	L-Tryptophan + H_2O $\rightarrow$ Indole + Pyruvate + NH_3
Decarboxylases	Lysine $\rightarrow$ Cadaverine
	Glutamate $\rightarrow$ Aminobutyric acid
	Tyrosine $\rightarrow$ Tyramine
	Tryptophan $\rightarrow$ Tryptamine
	Arginine $\rightarrow$ Putrescine
	Histidine $\rightarrow$ Histamine
Deaminases	Alanine $\rightarrow$ Pyruvate
	Tryptophan $\rightarrow$ Indole
	Glutamate $\rightarrow$ α-Ketoglutarate
	Serine $\rightarrow$ Pyruvate
	Threonine $\rightarrow$ α-Ketobutyrate

Table 1.8. Amino Acid Modifications

Amino Acid	Modification	Product
Arginine	Deamination	Citrulline
Glutamine	Deamination	Glutamic acid
Asparagine	Deamination	Aspartic acid
Various	C-terminal amidation	Amidated amino acid/protein
Serine	Phosphorylation	Phosphoserine
Histidine	Phosphorylation	Phosphohistidine
Tyrosine	Phosphorylation	Phosphotyrosine
Threonine	Phosphorylation	Phosphothreonine
Asparagine	Glycosylation	Various; *N*-linked glycoprotein
Serine	Glycosylation	Various; *O*-linked glycoprotein
Threonine	Glycosylation	Various; *O*-linked glycoprotein

to PPO for subsequent action on the phenolic ring of Tyr. Phenolics are hydroxylated, thus producing diphenols that are then subsequently oxidised to quinones:

$$2\,\text{Tyrosine O}_2 + \text{BH}_2 \rightarrow 2\,\text{Dihydroxylphenylamine} + \text{O}_2$$
$$\rightarrow 2\,\text{o-Benzoquinone} + 2\text{H}_2\text{O}$$

The action of PPO can be desirable in various food products, such as raisins, prunes, dates, cider and tea; however, the extent of browning needs to be controlled. The use of reducing compounds is the most effective control method for PPO browning. The most widespread anti-browning treatment used by the food industry was the addition of sulfiting agents; however, due to safety concerns (e.g. allergenic-type reactions), other methods have been developed, including the use of other reducing agents (ascorbic acid and analogues, Cys, glutathione), chelating agents (phosphates, EDTA), acidulants (citric acid, phosphoric acid), enzyme inhibitors, enzyme treatment and complexing agents (e.g. copolymerised β-cyclodextrin or polyvinylpolypyrrolidone; Sapers et al. 2002). Application of these PPO activity inhibitors is strictly regulated in different countries (Eskin 1990, Gopakumar 2000, Kim et al. 2000). Oxidative browning is one of three types of browning reactions important in food colour, the other two being non-oxidative/Maillard browning and caramelisation (covered above and extensively in food chemistry texts; see Damodaran et al. 2008).

ENZYMATIC TEXTURE MODIFICATIONS

Transglutaminase (TGase, EC 2.3.2.13, protein-glutamine-y-glutamyltransferase) catalyses acyl transfer between R group carboxyamides of glutamine residues in proteins, peptides and various primary amines; the ε-amino group of Lys acts as acyl acceptor, resulting in polymerisation and inter- or intra-molecular cross-linking of proteins via formation of ε-(-y-glutamyl) Lys linkages via exchange of the Lys ε-amino group for ammonia at the carboxyamide group of a glutamine residue. Formation of covalent cross-links between proteins is the basis for TGase-based modification of food protein physical properties. The primary applications of TGase in seafood processing have been for cold restructuring, cold gelation of pastes and gel-strength enhancement through myosin cross-linking.

QUALITY INDEX

Trimethylamine and its N-oxide have long been used as indices for freshness in fishery products. Degradation of trimethylamine and its N-oxide leads to the formation of ammonia and formaldehyde with undesirable odours. The pathway on the production of formaldehyde and ammonia from trimethylamine and its N-oxide is shown in Figure 1.3.

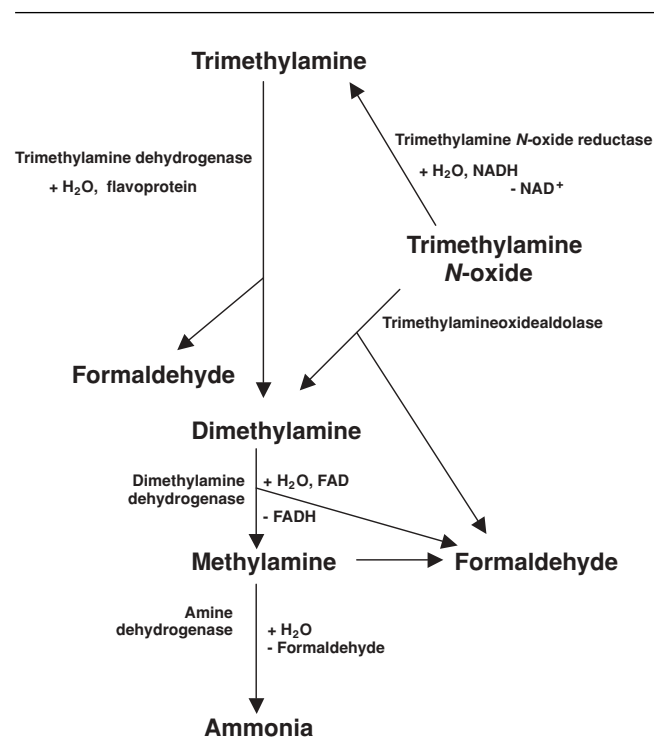
Most live pelagic and scombroid fish (e.g. tunas, sardines and mackerel) contain an appreciable amount of His in the free state. In post-mortem scombroid fish, the free His is converted by the bacterial enzyme His decarboxylase into free histamine. Histamine is produced in fish caught 40–50 hours after death when


Figure 1.3. Degradation of trimethylamine and its N-oxide. Trimethylamine N-oxide reductase (EC 1.6.6.9), trimethylamine dehydrogenase (EC 1.5.8.2), dimethylamine dehydrogenase (EC 1.5.8.1), amine dehydrogenase (EC 1.4.99.3). (From Haard et al. 1982, Gopakumar 2000, Stoleo and Rehbein 2000, IUBMB-NC website (www.iubmb.org).)

fish are not properly chilled. Improper handling of tuna and mackerel after harvest can produce enough histamine to cause food poisoning (called scombroid or histamine poisoning), resulting in facial flushing, rashes, headache and gastrointestinal disorder. These disorders seem to be strongly influenced by other related biogenic amines, such as putrescine and cadaverine, produced by similar enzymatic decarboxylation (Table 1.9). The presence of putrescine and cadaverine is more significant in shellfish, such as shrimp. The detection and quantification of histamine is fairly simple and inexpensive; however, the detection and quantification of putrescine and cadaverine are more complicated and expensive. Despite the possibility that histamine may not be the main cause of poisoning (histamine is not stable under strong acidic conditions such as the stomach), it is used as an index of freshness of raw materials due to the simplicity of histamine analysis (Gopakumar 2000).

Urea is hydrolysed by the enzyme urease (EC 3.5.1.5), producing ammonia, which is one of the components measured by total volatile base (TVB). TVB nitrogen has been used as a quality index of seafood acceptability by various agencies (Johnson and Linsay 1986, Cadwallader 2000, Gopakumar 2000). Live shark contains relatively high amounts of urea, thus under improper handling urea is converted to ammonia, giving shark meat an ammonia odour, which is a quality defect.

FRUIT RIPENING

Ethylene, a compound produced as a result of fruit ripening, acts as an initiator and accelerator of fruit ripening. Its concentration is low in green fruits, but can accumulate inside the fruit and subsequently activate its own production (positive feedback). Table 1.10 lists enzymes in the production of ethylene starting from methionine. Ethylene is commonly used to intentionally ripen fruit. During shipping of green bananas, ethylene is removed through absorption by potassium permanganate to render a longer shelf life.

ANALYTICAL PROTEIN BIOCHEMISTRY

The ability to isolate food proteins from complex materials/matrices is critical to their biochemical characterisation. Differing biochemical characteristics such as charge, isoelectric point, mass, molecular shape and size, hydrophobicity, ligand affinity and enzymatic activity all offer opportunities for separation. Charge and size/mass are commonly exploited parameters used to separate different proteins using ion exchange and size exclusion chromatography, respectively. In ion exchange chromatography, proteins within a sample are bound to a stationary phase having an opposite charge (e.g. anionic proteins are bound to a cationic column matrix). A gradient of competing ions is then passed through the column matrix such that weakly bound proteins will elute at low gradient concentration and thus are separated from strongly bound proteins. In the case of size-exclusion chromatography, protein mixtures are passed through an inert stationary phase containing beads having pores of known size. Thus, larger molecules will take a more direct (and hence faster) path relative to smaller molecules, which can fit into the beads, resulting in a more 'meandering', longer path, and therefore, elute slower (in comparison to larger molecules).

Perhaps the most basic biochemical analysis is the determination of molecular mass. Polyacrylamide gel electrophoresis (PAGE) in the presence of a detergent and a reducing agent is typically used for this purpose (mass spectrometry is used for precise measurement where possible). Detergent (sodium dodecyl sulphate; SDS) is incorporated to negate charge effects and to ensure all proteins are completely unfolded, thereby leaving only mass as the sole determinant for rate of travel through the gel and hence the term SDS-PAGE. Proteins denatured with SDS have a negative charge and, therefore, will migrate through the gel in an electric field (see Figure 1.4). A standard curve for proteins with known molecular masses consisting of relative mobility versus log [molecular mass] can be generated to calculate masses of unknowns run on the same gel.

FOOD ALLERGENICITY

The primary role of the immune system is to distinguish between self and foreign biomolecules in order to defend the host against invading organisms. Antibody proteins that are produced in response to the foreign compounds are specifically referred to as immunoglobulins (Ig), where five classes exist, which share common structural motifs: IgG, IgA, IgM, IgD and IgE. IgE, the least abundant class of antibodies, are the immunogenic proteins important to protection against parasites as well as the causative proteins in allergic reactions (Berg 2002).

Allergic diseases, particularly in industrialised countries, have significantly increased in the last two decades (Mine and Yang 2007). In the United States, food-induced allergies occur in an estimated 6% of young children and 3–4% of adults (Sicherer and Sampson 2006). The most common causes of food allergic reactions for the young are cow's milk and egg, whereas adults are more likely to develop sensitivity to shellfish

Table 1.10. Ethylene Biosynthesis

Enzyme	Reaction
Methionine adenosyltransferase (EC 2.5.1.6)	L-Methionine + ATP + $H_2O \rightarrow$ *S*-adenosyl-γ-methionine + Diphosphate + Pi
Aminocyclopropane carboxylate synthetase (EC 4.4.1.14)	*S*-adenosyl-γ-methionine $\rightarrow$ 1-Aminocyclopropane-1-carboxylate + 5′-Methylthio-adenosine
Aminocyclopropane carboxylate oxidase (EC 4.14.17.4)	1-Aminocyclopropane-1-carboxylate + Ascorbate + $\frac{1}{2}O_2 \rightarrow$ Ethylene +Dedroascorbate + CO_2 + HCN + H_2O

ported that the carbohydrate portion of ovomucoid contributed to binding human IgE (Matsuda et al. 1985); however, subsequent investigation suggested that it did not participate in protein allergenicity (Besler et al. 1997).

As a means of reducing the allergenicity of egg proteins, enzymatic treatments have been studied. The major limitations or potential hurdles to such an approach are the need for the allergen epitope(s) to be directly impacted, i.e. cleavage upon enzyme treatment, and the retaining of the unique functional properties of egg proteins in foods, e.g. foaming and gelling (Mine et al. 2008). A combination of thermal treatments and enzymatic hydrolyses resulted in a hydrolysed liquid egg product with 100 times less IgE-binding activity than the starting material, determined by analysis of human subjects having egg allergies (Hildebrt et al. 2008). Flavour and texturising properties were not altered when incorporated into various food products, suggesting potential to manufacture customised products accessible to egg-allergy sufferers (Mine et al. 2008).

ENZYME BIOTECHNOLOGY IN FOODS

Various enzymes are used as processing aids in the food industry. Examples include acetolactate decarboxylase, α-amylase, amylo-l,6-glucosidase, chymosin, lactase and maltogenic α-amylase (Table 1.11), many of which are produced as recombinant proteins using genetic engineering techniques. Recombinant expression has the advantage of providing consistent enzyme preparations since expression cultures can be maintained indefinitely, and it is not dependent on natural sources (e.g. chymosin from calf stomachs). In addition to recombinant enzymes, microbial enzymes are also used, e.g. microbial rennets are used in cheese production from several organisms: *Rhizomucor pusillus, R. miehei, Endothia parasitica, Aspergillus oryzae and Irpex lactis.* Trade names of microbial milk-clotting enzymes include Rennilase, Fromase, Marzyme and Hanilase. Other enzymes include lactase, which is well accepted by the dairy industry for the production of lactose-free milk for lactose-intolerant consumers, and amylases, which are used for the production of high-fructose corn syrup and as an anti-stalling agent for bread.

FOOD LIPID BIOCHEMISTRY

FATTY ACIDS

Lipids are organic compounds characterised by little or no solubility in water and are the basic units of all organisms' membranes, the substituent of lipoproteins and the energy storage form of all animals. The basic units of lipids are fatty acids (FAs), simple hydrocarbon chains of varying length with a carboxylic acid group at one end.

$$CH_3 - [CH_2]_n - COOH$$

The carboxylic carbon is designated as carbon 1 (C1). FAs are characteristically named using hydrocarbon chain length. For example, a four carbon FA is butanoic acid, a five carbon FA is pentanoic acid, a six carbon FA is hexanoic acid etc.,
Figure 1.4. SDS-PAGE gel with protein standards of known masses (right lane), impure target protein (left lane) and pure target protein (middle lane; ***). The target protein was calculated to have a molecular mass of 11,700 Daltons (Da) or 11.7 kDa.

(Sampson 2004). Such reactions are thought to result from an abnormal response of the mucosal immune system towards normally harmless dietary proteins (antigens; Bischoff and Crowe 2005). Allergic reactions are distinct from food intolerances that do not involve the immune system (Sampson and Cooke 1990).

One of the biggest problems with food allergy management is that avoidance of antigen is the primary means of preventing allergic reactions; however, minute amounts of so-called 'hidden allergens' in the form of nut, milk and egg contaminants occur in many processed foods. To avoid allergens entirely may pose the risk of avoiding nutritionally important foods, resulting in malnutrition, especially in the young, a problem highlighting the need for control of allergens in foods including the making of hypoallergenic food products (Mine and Yang 2007). Allergic reactions to food components that are mediated by IgE are the best understood and most common type (Type I; Ebo and Stevens 2001).

In general, glycosyl biomolecules are often important elicitors of immunogenic responses (Berg 2002), e.g. bacterial lipopolysaccharides. Many proteins contain carbohydrate moieties and are termed 'glycoproteins'. IgE specific to glycans has been reported (van Ree et al. 1995), and it was originally re-

Table 1.11. Selected Commercial Biotechnology-Derived Food Enzymes

Enzyme	Application
Acetolactate decarboxylase (EC 4.1.1.5)	Beer aging and diacetyl reduction
α-Amylase (EC 3.2.1.1)	High-fructose corn syrup production
Amylo-1,6-glucosidase (EC 3.2.1.33)	High-fructose corn syrup production
Chymosin (EC 3.4.23.4)	Milk clotting in cheese manufacturing
Lactase (EC 3.2.1.108)	Lactose hydrolysis
Glucan-1,4-α-maltogenic α-amylase (EC 3.2.1.133)	Anti-stalling in bread

Figure 1.5. The structures of *cis*- and *trans*-oleic acid.

with designations 4:0, 5:0 and 6:0, respectively, with the first digit indicating the number of carbons and the second giving the number of double bonds. For FAs containing double bonds, hexadecanoic acid (16:0) becomes hexadecenoic acid (16:1), 16:2 is termed hexadecadienoic acid, indicating two double bonds, and 16:3 is hexadecatrienoic acid. Following this convention and in order to indicate the position of the double bond, if 16:1 has its double bond between C7 and C8, then 7-hexadecenoic acid is used.

Currently, the term 'omega' is often used. In this case, the methyl end of the FA is termed the omega carbon (ω); therefore, 9,12-octadecadienoic acid (18:2) becomes 18:2 ω-6 since the first double bond is six carbons from the ω carbon. Table 1.12 shows some common FAs, their lengths, and double bond characteristics. When discussing FAs, the term double bond simply indicates the lack of hydrogen across a hydrocarbon bond:

—CH=CH— (double bond; unsaturated)

vs.—CH2—CH2— (saturated)

Geometrically, double bonds can be either *cis* or *trans*, with the cis configuration being the naturally occurring form, bulky and susceptible to oxidation. The trans configuration is more linear, has properties similar to a saturated FA and is not found in nature (see Figure 1.5).

TRIGLYCERIDES AND PHOSPHOLIPIDS

In foods, most lipids exist as triglycerides (TGs), making up 98% of food lipids. The name triglyceride refers to its biochemical structure consisting of a glycerol having three FAs bound at its hydroxyl groups. TGs are the primary energy storage form in animals, seeds and certain fruits (e.g. avocado and olive). In comparision to carbohydrates, TGs provide more than double the energy, on a dry basis (9 kcal/g vs. 4 kcal/g). Food TGs also provide mouthfeel and satiety as well as aid in the provision and absorption of fat-soluble vitamins (i.e. A, D, E and K). In terms of food structure, TGs play critical roles in the structures of emulsified food products (oil and water mixtures) like ice cream and chocolate. In ice cream, liquid fat globules partially

Table 1.12. Selected Common Fatty Acids

Fatty Acid	Systematic Name	Number of Carbons	Abbreviation
Butyric	Butanoic	4	4:0
Lauric	Dodecanoic	12	12:0
Myristic	Tetradecanoic	14	14:0
Palmitic	Hexadecanoic	16	16:0
Stearic	Octadecanoic	18	18:0
Oleic	9-octadecenoic	18	18:1 (*n*-9)
Linoleic	9,12-octadecadienoic	18	18:2 (*n*-6)
Linolenic	9,12,15-octadecatrienoic	18	18:3 (*n*-3)
Arachidonic	5,8,11,15-eicosatetraenoic	20	20:4 (*n*-6)

aggregate until a continuous network forms (partial coalescence) yielding a 'solid' product. TG globules cement to one another at globule interfaces due to interacting fat crystal networks (Goff 1997).

The physical and functional properties of TGs are highly variable and are dependent on FA chain length, number of FA double bonds and position/order of FAs on the glycerol backbone (e.g. oil seeds tend to contain more double bonds in the middle position, whereas animal TGs contain saturated FAs at this position). Furthermore, reactions such as oxidation or lipolysis affect TG behaviour.

PHOSPHOLIPIDS

Another class of lipids are phospholipids (PLs), most of which consist of a glycerol backbone with two FAs and the third backbone position containing various substituents such as serine, choline and ethanolamine. These polar substituents render PLs amphipathic (one end hydrophilic, the other FA end hydrophobic). An example of a PL used in food is lecithin, a natural emulsifier and surfactant. In aqueous environments, PLs spontaneously form phospholipid bilayers in spherical-shaped structures called liposomes or lipid vesicles. Liposomes have been used for the study of membrane properties and substance permeabilities, drug delivery, and can be used for microencapsulation of food ingredients. Encapsulation of vitamin C significantly improves shelf life by about 2 months when degradative components like copper, Lys and ascorbate oxidase are present. Also, ingredients can be sequestered within liposomes that have well-defined melting temperatures, thus releasing the contents in a controlled fashion (Gouin 2004).

FOOD LIPID DEGRADATION

Hydrolysis and oxidation reactions are the principal ways in which TGs are degraded in foods. Lipolysis refers to the hydrolysis of the ester linkage between the glycerol backbone and FAs, thereby releasing free FAs. Lipases are enzymes that release FAs from the outer TG positions by hydrolysis. Free FA's are more susceptible to oxidation and they are more volatile compared to FAs within TGs. Lipase activity is potentially problematic post-slaughter, and controlling temperature minimises their activities.

By contrast, oil seeds 'naturally' undergo lipolysis pre-harvest and, therefore, contain a significant amount of free FAs, resulting in acidity that should be neutralised in the extracted oil. In terms of dairy products such as cheeses, yoghurts and bread, controlled lipolysis is used as a means of producing desired odours and flavours via microbial and endogenous lipases. However, lipolysis is also responsible for development of rancid flavour in milk, resulting from the release of short chain FAs, e.g. butyric acid. Deep frying also produces undesirable lipolysis due to the high heat and introduction of water from foods cooked in the oil medium.

During seed germination, lipids are degraded enzymatically to serve as an energy source for plant growth and development. Because of the presence of a considerable amount of seed lipids in oilseeds, they have attracted the most attention, and various pathways in the conversion of FAs have been reported (Table 1.13). The FAs hydrolysed from the oilseed glycerides are further metabolised by β-oxidation followed by the citric acid cycle to produce energy. Seed germination is important in the production of malted barley flour for bread making and brewing.

AUTOXIDATION

The principal cause of lipid oxidation is *autoxidation*. This process takes place via the action of free radicals on the FA hydrocarbon chain in a chain reaction. Initiation of the chain reaction is the creation of free radicals by metal catalysis, light or peroxide decomposition. The initial free radicals then act on the FA by abstracting a hydrogen atom from the hydrocarbon chain, thereby making a new free radical, which then reacts with O_2, resulting in hydroperoxy free-radical formation of the FA. This FA-free radical then acts on other FAs abstracting a hydrogen atom, creating a new free radical and the formation of a stable hydroperoxide. The chain reaction terminates when two free radicals react together.

Initiation -- creation of $R^\bullet$
Propagation -- $R^\bullet + O^2 \rightarrow ROO^\bullet$
$ROO^\bullet + RH \rightarrow ROOH + R^\bullet$
(the new free radical can react with O_2 anew)
Termination -- $R^\bullet + R^\bullet$
$R^\bullet + ROO^\bullet$
$ROO^\bullet + ROO^\bullet$

Table 1.14. Enzymatic Lipid Oxidation in Food Systems

Enzyme	Reaction
Arachidonate-5-lipoxygenase (5-lipoxygenase, EC 1.13.11.34)	Arachidonate + O_2 → (6*E*,8*Z*,11*Z*,14*Z*)-(5*S*)-5-hydroperoxyicosa-6–8-11,14-tetraenoate
Arachidonate-8-lipoxygenase (8-lipoxygenase, EC 1.13.11.40)	Arachidonate + O_2 → (5*Z*,9*E*,11*Z*,14*Z*)-(8*R*)-8-hydroperoxyicosa-5,9,11,14-tetraenoate
Arachidonate 12-lipoxygenase (lipoxygenase, EC 1.13.11.31)	Arachidonate + O_2 → (5*Z*,8*Z*,10*E*,14*Z*)-(12*S*)-12-hydroperoxyicosa-(12–5,8,10,14-tetraenoate)

Lipoxygenase (EC 1.13.11.12)	Linoleate + O_2 → (9*Z*,11*E*)-(13*S*)-13-hydroperoxyoctadeca-9,11-dienoate

Source: Lopez-Amaya and Marangoni 2000a, 2000b, Pan and Kuo 2000, Kolakowska 2003, IUBMB-NC website (www.iubmb.org).

Another mode of lipid oxidation is enzyme-catalysed lipid oxidation by a group of enzymes termed lipoxygenases (LOXs), whose activities are important in legumes and cereals. In LOX activity, a free radical of a FA initially is formed, followed by its reaction with O_2, yielding a hydroperoxide product (Klinman 2007). Linoleic acid and arachidonic acid are important FAs from the health perspective and are quite common in many food systems (Table 1.12). Because of the number of double bonds in arachidonic acid, enzymatic oxidation can occur at various sites, and the responsible LOXs are labelled according to these sites (Table 1.14). In addition to rancid off-flavours, LOX can also cause deleterious effects on vitamins and colour compounds. However, LOX activity also causes the pleasant odours associated with cut tomatoes and cucumbers.

The main enzymes involved in the generation of the aroma in fresh fish are also LOXs, specifically the 12- and 15-LOXs (Table 1.14) and hydroperoxide lyase. The 12-LOX acts on specific polyunsaturated FAs and produces *n*-9-hydroperoxides. Hydrolysis of the 9-hydroperoxide of eicosapentenoic acid by specific hydroperoxide lyases leads to the formation of aldehydes that undergo reduction to their corresponding alcohols, a significant step in the general decline of the aroma intensity due to alcohols having higher odour detection thresholds than the aldehydes (Johnson and Linsay 1986, German et al. 1992).

Milk contains a considerable amount of lipids and these milk lipids are subjected to enzymatic oxidation during cheese ripening. Under proper cheese maturation conditions, these enzymatic reactions starting from milk lipids create the desirable flavour compounds for these cheeses. These reactions are numerous and not completely understood, thus only general reactions are provided (Table 1.15). Readers should refer to Chapters 19, 20 and 26 in this book for a detailed discussion.

ELECTED PHYTOCHEMICAL FLAVOUR AND COLOUR COMPOUNDS

Many fruits and vegetables produce flavours that are significant in their acceptance and handling. There are a few well-known examples (Table 1.16). Garlic is well known for its pungent odour due to the enzymatic breakdown of its alliin to the thiosulfonate allicin, with the characteristic garlic odour. Strawberries have a very recognisable and pleasant odour when they ripen. Biochemical production of the key compound responsible for strawberry flavour, the furan 2,5-dimethyl-4-hydroxy-2H-furan-3-one (DMHF), is also known as furaneol, which results from hydrolysis of terminal, non-reducing ∼-D-glucose residues from DMHF-glucoside with release of ∼-D-glucose and DMHF. Lemon and orange seeds contain limonin, a furanolactone that is bitter and is hydrolysable to limonate, which is less bitter. Many cruciferous vegetables such as cabbage and broccoli have a sulfurous odour due to the production of a thiol compound (R–SH) after enzymatic hydrolysis of its glucoside. Brewed tea darkens

Table 1.15. Changes in Lipids in Cheese Manufacturing

Enzyme	Reaction
Lipolysis	
Lipases, esterases	Triglycerides → β-Keto acids, acetoacetate, fatty acids
Acetoacetate decarboxylase (EC 4.1.1.4)	Acetoacetate + H^+ → Acetone + CO_2
Acetoacetate-CoA ligase (EC 6.2.1.16)	Acetoacetate + ATP + CoA → Acetyl CoA + AMP + Diphosphate
Esterases	Fatty acids → Esters
Conversion of fatty acids	
β-Oxidation and decarboxylation	β-Keto acids → Methyl ketones

after it is exposed to air due to enzymatic oxidation (discussed earlier). Flavours from cheese fermentation and fresh-fish odour have already been described earlier, and formation of fishy odour will be described later.

Colour is an intrinsic property of foods, and therefore, a change in colour is often caused by a change in quality. Vision is the most important sensory perception in selecting food and appreciating its quality (Diehl 2008). Chlorophylls are the most abundant natural pigments and are responsible for the green colour of plants (Marquez Ursula and Sinnecker 2008) and are the biomolecules responsible for capturing light energy in its transformation into chemical energy during photosynthesis. Light is able to be absorbed very efficiently due to the presence of many conjugated double bonds within the large, multi-ring chlorophyll structure. Disappearance of chlorophyll during fruit ripening and leaf senescence indicates slowing of photosynthesis. The loss of green colour is due to a loss of chlorophyll structure via two main stages: First, various reactions produce greenish chlorophyll derivatives and second, oxidative reactions result in opening of ring structures, thereby causing colourless products (Diehl 2008).

Carotenoids are the most widely distributed group of pigments, and although they are not produced by the human body,

they are essential to human health. Vitamin A/β-carotene are carotenoids critical to a healthy diet. Additionally, carotenoids may help reduce the risk of cancer and heart disease (Bertram 1999), are important natural colourants in foods and are used as sources of red, yellow and orange food colouring (Otles and Cagindi 2008). Carotenoids are fat-soluble pigments that provide the colour for many common fruits such as yellow peaches, papayas and mangoes. During post-harvest maturation, these fruits show intense yellow to yellowish orange colours due to synthesis of carotenoids from its precursor isopentyl diphosphate, which is derived from (R)-mevalonate. Isopentyl diphosphate is a key building block for carotenoids (Croteau et al. 2000), and Table 1.17 lists the sequence of reactions in the formation of (R)-mevalonate from acetyl-CoA and from (R)-mevalonate to isopentyl diphosphate.

Flavonoids are not only a group of compounds responsible for various red, blue or violet colours of fruits and vegetables, they are also related to the group of bioactive, anti-plant pathogen compounds called stilbenes. Stilbenes have a common precursor of *trans-cinnamate* branching out into two routes, one that leads to flavonoids and the other leading to stilbenes (Table 1.18). Table 1.18 gives the series of reactions in the biosynthesis of naringenin chalcone, the building block for flavonoid

Table 1.17. Mevalonate and Isopentyl Diphosphate Biosyntheses

Enzyme	Reaction
Acetyl-CoA C-acetyltransferase (EC 2.3.1.9)	2 Acetyl-CoA $\rightarrow$ Acetoacetyl-Co-A + CoA
Hydroxymethylglutaryl-CoA-synthase (EC 2.3.3.10)	Acetoacetyl-CoA + Acetyl-CoA + H_2O $\rightarrow$ (S)-3-Hydroxy-3-methylglutaryl CoA + CoA
Hydroxymethylglutaryl-CoA reductase (EC 1.1.1.34)	(S)-3-Hydroxy-3-methylglutaryl-CoA + 2 $NADPH_2$ $\rightarrow$ (R)-Mevalonate + CoA + 2 NADP
Mevaldate reductase (EC 1.1.1.32)	(R)-Mevalonate + NAD $\rightarrow$ Mevaldate + $NADH_2$
Mevalonate kinase (EC 2.7.1.36)	(R)-Mevalonate + ATP $\rightarrow$ (R)-5-Phosphomevalonate + ADP
Phosphomevalonate kinase (EC 2.7.4.2)	(R)-5-Phosphomevalonate + ATP $\rightarrow$ (R)-5-Diphosphomevalonate + ADP
Diphosphomevalonate decarboxylase (EC 4.1.1.33)	(R)-5-Diphosphomevalonate + ATP $\rightarrow$ Isopentyl diphosphate + ADP + Pi + CO2

biosynthesis. Considerable interest has been given to the stilbene trans 3,5,4′ -trihydroxystilbene commonly called resveratrol in red grapes and red wine that may have human nutraceutical and/or pharmaceutical applications (Narayanan et al. 2009). Table 1.19 summarises various phytochemicals and their sources that are thought to confer health benefits (Gropper 2009).

CHOLESTEROL

Cholesterol is an important lipid in animal biochemical processes that controls the fluidity of membranes and is the precursor for all steroid hormones. Cholesterol's structure is made up of adjacent carbon rings, making it hydrophobic (fat soluble), and thus it must be transported through the blood complex as a lipoprotein in structures called chylomicrons. The densities

of lipoproteins vary greatly; an excessive level of low-density lipoprotein (LDL) is a critical risk factor for heart disease. In contrast, plants produce related molecules called phytosterols, which have various nutraceutical applications (Kritchevsky and Chen 2005).

TERPENOIDS

Terpenoids, a diverse and complex chemical group, are lipid-type molecules important to flavours and aromas of seasonings, herbs and fruits. Most terpenoids are multi-cyclic compounds made via successive polymerisation and cyclisation reactions derived from the 5-carbon building block isoprene, which contains two double bonds. Terpenoids are components of the flavour profiles of most soft fruit (Maarse 1991). In some fruit species, they are of great importance for the characteristic flavour and aroma

Table 1.19. Phytochemicals and Their Sources

	Phytochemical	Source
Anthocyanins	Cyanidin	Berries, cherries, plums, red wine
Carotenoids	β-carotene, α-carotene, lutein, lycopene	Tomato, pumpkin, squash, carrot, watermelon, papaya, guava
Flavanols	Catechins, epicatechins	Green tea, pear, wine, apple
Flavones	Apigenin, luteolin	Parsley, some cereals
Flavonols	Quercetin, kaempferol, myricetin	Onions, tea, olive, kale, leaf lettuce, cranberry, tomato, apple, turnip green, endive, *Gingko biloba*
Glucosinolates	Gucobrassicin, gluconapin, sinigrin, glucoiberin	Broccoli, cabbage, Brussels sprouts, mustard, watercress
Isoflavones	Genistein, daidzein, equol	Soy, nuts, milk, cheese, flour, miso, legumes
Isothiocyanates	Allylisothiocyanates, indoles, sulforaphane	Broccoli, cabbage, Brussels sprouts, mustard, watercress
Lignans	Secoisolariciresinol, mataresinol	Berries, flaxseed, nuts, rye bran
Organosulfides	Diallyl sulphide, allyl methyl sulphide, *S*-allylcysteine	Garlic, onions, leeks, broccoli, cabbage, brussel sprouts, mustard, watercress
Phenolic acids	Hydroxycinnamic acids (caffeic, ferukic, chlorogenic, curcumin) and hydroxybenzoic acids (ellagic, gallic)	Blueberry, cherry, pear, apple, orange, grapefruit, white potato, coffee bean, St. John's wort, *Echinacea*, raspberry, strawberry, grape juice
Phytosterols	β-Sitosterol, campesterol, stigmasterol	Oils: soy, rapeseed, corn, sunflower
Saponins	Panaxadiol, panaxatriol	Alfalfa sprouts, potato, tomato, ginseng
Terpenes	Limonene, carvone	Citrus fruits, cherries, *Gingko biloba*

(e.g. citrus fruits are high in terpenoids as is mango; Aharoni et al. 2004).

NUCLEIC ACIDS AND FOOD SCIENCE

DNA STRUCTURE

Although nucleic acids are not generally important components of foods, they are perhaps (and ironically) the most important biomolecule class of all for the simple reason that everything we eat was at some point alive, and every process and structure in those organisms were determined via enzymes encoded for by DNA. Indeed, the entire purpose of breeding programs is to control the propagation of DNA between successive generations. Understanding the basics of DNA (deoxyribonucleic acid) and its biochemical forms is important for food scientists to gain an appreciation of the basis for genetic manipulations of food-related proteins as well as DNA-based food authentication techniques.

DNA is composed of three main chemical components: a nitrogenous base, a sugar and a phosphate. There are four bases: Adenine (A) and guanine (G) are purines, while thymine (T) and cytosine (C) are pyrimidines. The bases bound to both the sugar and phosphate moieties make up nucleotides and the four building blocks of DNA are deoxyadenosine triphosphate, deoxyguanosine triphosphate, deoxythymidine triphosphate and deoxycytidine triphosphate (dATP, dGTP, dTTP and dCTP, respectively). These building blocks are typically referred to as 'bases' or simply A, T, G and C; however, common usage of these terms are meant to imply nucleotides as opposed to bases alone. The nucleotides covalently bond together forming a DNA strand that is synthesised by DNA polymerase. Additionally, each nucleotide's base moiety can bond via hydrogen bonds to other bases; A–T and G–C, termed base pairs and are said to be complementary. In fact, DNA exists in two-stranded form, consisting of two complementary strands. For example, a strand ATCG would be paired to its complement TAGC.

```
5'-ATCG-3'
3'-TAGC-5'
```

Two-stranded DNA spontaneously forms a helix, hence the term double helix, which can contain many thousands of base pairs with molecular weights in the millions, or billions, of Daltons. By comparison, the largest known protein is a mere 3 million Daltons. *Genes* are stretches of DNA that encode for the synthesis of proteins; DNA is transcribed, yielding messenger RNA (mRNA), which is then translated at ribosomes, yielding specific sequences of amino acids (proteins).

GENETIC MODIFICATION

The advances in how to copy DNA, modify its sequence, and transfer genes between organisms efficiently and at low cost has produced a tremendous ability to study the roles of specific proteins in organisms as well as the roles of specific amino acids within proteins. This ability has produced an alternate

to traditional breeding programs in the search for food plants and animals that have desired traits, such as increased yield, increased pesticide tolerance, lower pesticide requirements/higher pest resistance, longer shelf life post-harvest, etc. This alternate strategy is the basis of genetic modification (GM).

Critical to the study, transfer and manipulation of genes was the advent of the polymerase chain reaction (PCR), which allows for the easy and accurate copying and, equally important, the amplification of DNA sequences. Briefly, PCR works by inducing repeated copying of a given DNA sequence by the enzyme DNA polymerase via repeated temperature cycles such that exponential amplification results, i.e. the first round yields only a doubling, but the second round then makes new copies of each of the first round's copies and the originals; 2, 4, 8, 16, 32, 64, 128, etc. After 25–30 PCR rounds, millions of copies result. Thus, a gene encoding for a useful gene in organism A (e.g. an anti-freeze protein) can be copied, amplified and subsequently transferred to organism B (e.g. a fruit).

An example of GM is that of the Flavr savr™ tomato, originally available for consumption in 1994 (Martineau 2001). A non-sense gene is a DNA sequence that encodes for complementary mRNA, which base-pair matches and binds to a natural gene transcript, thereby suppressing its translation. A 'non-sense', gene acting against the polygalacturonase gene, an enzyme responsible for the breakdown of a cell-wall component during ripening, was incorporated into a strain of tomato. The result was slowed softening of the texture of the engineered tomato compared to normal tomatoes, thus allowing producers to vine-ripen the Flavr savr™, reducing losses (e.g. bruising) during subsequent transport to market. Superior flavour and appearance relative to natural tomatoes picked green, as well as equivalent micro- and macronutrient content, pH, acidity and sugar content relative to non-transgenic tomatoes resulted.

In terms of food processing, lactic acid bacteria and yeast have been developed to solve problems in the dairy, baking and brewing industries (Tables 1.20 and 1.21). As with biotechnology-derived food enzymes, the use of genetically modified organisms is governed by laws of nations or regions (e.g. the European Union).

Safety assessments of GM foods before being released to market are done. These comparisons to non-engineered, conventional counterparts include proximate analysis as well as analyses of nutritional components, toxins, toxicants, anti-nutrients and other components relevant to given cases. As well, animal feeding trials are conducted to determine if any adverse health effects are observable (Institute of Medicine and National Research Council of the National Academies 2004). Ideally, the reference food for the above comparisons is the isogenic food (i.e. non-transformed) from which the GM version was derived.

FOOD AUTHENTICATION AND THE ROLE OF DNA TECHNOLOGIES

Another area utilising DNA technology is *food authentication*. Analysing processed food and ingredients for the presence of fraudulent or foreign components by DNA technologies can be

Table 1.20. Selected Commercial Biotechnology-derived Food Enzymes

Enzyme	Application
Acetolactate decarboxylase (EC 4.1.1.5)	Beer aging and diacetyl reduction
α-Amylase (EC 3.2.1.1)	High-fructose corn syrup production
Amylo-1,6-glucosidase (EC 3.2.1.33)	High-fructose corn syrup production
Chymosin (EC 3.4.23.4)	Milk clotting in cheese manufacturing
Lactase (EC 3.2.1.108)	Lactose hydrolysis
Glucan-1,4-α-maltogenic α-amylase (EC 3.2.1.133)	Anti-stalling in bread

very complex due to degradation of genetic material as the result of processing conditions. Detecting misrepresentation of food components is a task well-suited for DNA-based detection in the case of meat species of origin, especially when the meat product is processed such that appearance and physical traits cannot easily cue experts as to product identity. Gene sequences within mitochondrial DNA are usually used as the PCR targets for such purposes (Wiseman 2009). For example, different tuna species can be differentiated (Michelini et al. 2007). Likewise, the presence of meat in cattle feed can be assayed (Rensen 2005). Such tests can be done for high-heat-processed samples at a low cost, and such tests can be highly automated for steps post sample collection. Lastly, another example of a food authentication application for PCR is the case of detecting the presence and/or the quantity of genetically modified ingredients in a food. For the purposes of quantification, real-time PCR must be used (Wiseman 2009), the most modern type of PCR technology, because it is capable of highly precise, quantitative determinations. This capability is due to real-time PCR's ability to very quickly and accurately modulate PCR reaction temperature via the use of low-volume reactions. Jurisdictions that have

Table 1.21. Selected Genetically Modified Microorganisms Useful in Food Processing

Microorganism	Application
Lactobacillus lactis	Phage resistance, lactose metabolism, proteolytic activity, bacteriocin production
Saccharomyces cerevisiae (Baker's yeast, Brewer's yeast)	Gas (carbon dioxide) production in sweet, high-sugar dough
	Manufacture of low-calorie beer (starch degradation)

GM labelling laws (e.g. the European Union) can thus verify the correct labelling of incoming ingredients.

In the authentication process, DNA within foods can also be characterised and differentiated by use of *DNA probes*, an earlier food authentication technology that dates back to at least 1990, where it was used to distinguish between heat-processed ruminant (goat, sheep and beef), chicken and pig meat (Chicuni et al. 1990). DNA probes are short pieces of DNA (Rensen et al. 2005) that contain a detectable feature (usually fluorescence) and that are complementary to a DNA sequence of interest. Thus, a signal is produced only if the probed sequence is present in the food, since the probe will bind only to its complement in a manner that yields a signal. In order to probe a food product, genetic material is isolated and immobilised on a piece of nitrocellulose (blotting), which is then 'probed' with a DNA complementary probe. The information from the above types of DNA-based authentication tests can aid in processing quality control to ensure both authenticity and safety at relatively cheap cost.

NATURAL TOXICANTS

The contamination of various foods by toxicants may occur as a result of microbial production, crop plant production or ingestion by animals for human consumption. Microbial sources of toxins are mycotoxin-producing fungi and toxin-producing bacteria. Notable examples of microbially derived toxins are botulinum toxin produced by *Clostridium botulinum* and the *Staphylococcus aureus* toxin. These toxins are produced in the food itself and result in food poisoning. Both toxins are heat-labile; however, the extreme toxicity of the botulinum toxin, potent at 10^{-9} g per kg body weight, makes it of particular concern for food processing of anaerobically stored foods.

Mycotoxins are extremely toxic compounds produced by certain filamentous fungi in many crop plants (Richard 2007). Ingestion of mycotoxins can be harmful to humans via contaminated foods or feed animals via their feed, particularly in maize, wheat, barley, rye and most oilseeds. Mycotoxins produce symptoms that include nervous system disorders, limb loss and death. Aflatoxins are a well-studied type of mycotoxin that are known carcinogens. An example of a mycotoxin structure, aflatoxin B1, is shown in Figure 1.6. Mycotoxin poisoning can take place either directly or indirectly, through consumption of a contaminated food or by a food ingredient that may be contaminated and subsequently eaten as part of a final product.
Figure 1.6. The structure of aflatoxin B1, produced by *Aspergillus flavus* and *A. parasiticus*.
Figure 1.7. The structure of saxitoxin responsible for paralytic shellfish poisoning.

An important example of food-related mycotoxins is 'ergot', the common name for fungi of the genus *Claviceps*. Ergot species produce ergot alkaloids, which are derivatives of lysergic acid, isolysergic acid or dimethylergoline. When ingested, the various alkaloids produce devastating symptoms such as vasoconstriction, convulsion, gastrointestinal upset and central nervous system effects (Peraica et al. 1999)

Another type of natural toxins is that of shellfish toxins (phycotoxins), which are produced by certain species of marine algae and cyanobacteria (blue-green algae). The best known algal toxins are saxitoxins, responsible for paralytic shellfish poisoning (PSP; see Figure 1.7 for chemical structure). Saxitoxins block voltage-gated sodium channels of nerve cells. Thus, this group of 20 toxins induces extreme symptoms, including numbness, tingling and burning of the lips and skin, giddiness, ataxia and fever; severe poisoning may lead to muscular incoordination, respiratory distress or failure (Garthwaite 2000). The poisoning results from bioaccumulation of the algal toxins in algae-eating organisms and toxins can be step-wise passed up the food chain, e.g. from marine algae to shellfish to crabs to humans.

CONCLUSION

In 1939, the newly formed IFT was the world's first organisation to organise and coordinate those working in food processing, chemistry, engineering, microbiology and other sub-disciplines in order to better understand food systems. Food science began mainly within commodity departments, such as animal science, dairy science, horticulture, cereal science, poultry science and fisheries. Now, most of these programs have evolved into food science, or food science and human nutrition, departments. Many food science departments with a food biochemistry emphasis are now available all over the world. In addition, food science departments developed not only applied research programs, but also basic research programs that seek to understand foods at the atomic, molecular and/or cellular levels. The 'cook 'n' look, approach is not food science. Food science is a respected part of academic programmes worldwide, whose researchers often form collaborations with physicists, chemists, parasitologists, etc. Over the past several decades, food biochemistry research has led to industry applications, e.g. lactase supplements, lactose-free dairy products, Beano™, application of transglu-

taminase to control seafood protein restructuring, protease-based meat marinades for home, production of high-fructose syrups, rapid pathogen detection tests, massively diversified natural and artificial flavourings and many more. Thus, food biochemistry will continue to play critical roles in developments in food microbiology, packaging, product development, processing, crop science, nutrition and nutraceuticals.

Analytical Techniques in Food Biochemistry

Massimo Marcone

Abstract: Food is a very complex heterogeneous "material" composed of thousands of different nutritive and nonnutritive compounds embedded in a variety of different plant and animal matrices. Nondesirable biochemical compounds such as environmental contaminants, microbial and plant toxins, and veterinary drugs are also present with their presence posing a danger to human health. In analytical food chemistry, the isolation, identification, and quantification of both desirable and undesirable compounds continue to pose immense challenges to food analysts. Methods and tests used to isolate, identify, and quantify must be precise, accurate, be increasing sensitive to satisfy the rigors of investigative and applicable science, have minimal interfering factors, use minimal hazardous chemicals, and produce minimal/no hazardous wastes.

This chapter is mainly concerned with the analytical methods used to determine the presence, identity, and quantity of all compounds of interest in a food. Although it is impossible to address the quantitative analysis of all food components, the major techniques used in food analysis will be addressed in detail. The food analyst has a variety of available tests but the test choice is primarily dependent on the goal of the analysis and the use of the final data. Many of the traditional analytical biochemical tests such as Kjeldahl digestion for protein determination are still regarded as the gold standard and is still used in many laboratories.

While useful, traditional analytical methods are continually being challenged by technological and instrumental developments. Technology is moving chemical analysis toward the use of more sophisticated instruments (either individually or in tandem) as both instrumental specificity and sensitivity are continually being "pushed"

to new limits. Gas chromatography (GC), high performance liquid chromatography (HPLC), spectroscopy including near infrared (NIR), and mass spectroscopy (MS) are now considered to be basic laboratory equipment used in food analysis. Tandem hybrid analytical equipment such as GC-MS is also gradually becoming common although it is more sophisticated than the single analytical tests.

PROTEIN ANALYSIS

Proteins are a large diverse group of nitrogenous organic compounds that are indispensable constituents in the structure and function of all living cells. They contribute to a wide variety of functions within each cell, ranging from structural materials such as chitin in exoskeletons, hair, and nails to mechanical functions such as actin and myosin in muscular tissue. Chemically, they influence pH as well as catalyze thousands of critical reactions, producing a variety of essential substances that are involved in functions such as cell-to-cell signaling, immune responses, cell adhesion, cell reproduction, etc.

Proteins are essentially polymers of 20 L-∞-amino acids bonded together by covalent peptide bonds between adjacent carboxyl and amino functional groups. The sequence of these amino acids, and thus the function and structure of the protein, is determined by the base pairs in the gene that encodes it. These 20 different amino acids interact with each other within their own chain and/or with other molecules in their external environment, which also greatly influences their final structure and function. Proteins are by definition relatively "heavy" organic molecules ranging in weight from approximately 5000 to more than a million Daltons and, over the years, many of these food proteins have been purified, identified, and characterized. Chemically speaking, nitrogen is the most distinguishing element in proteins, varying in amounts from 13% to 19% due to the variations in the specific amino acid composition of proteins (Chang 1998).

For the past several decades, protein analysis from food products has been performed by determining the nitrogen content after complete acid hydrolysis and digestion by the Kjeldahl method followed by an analytical step in which the resulting ammonium ion is quantified by titrimetry, colorimetry, or by the use of an ion-specific electrode. The result is then multiplied by a pre-established protein conversion factor that determines the final protein content of the sample (Chang 1998, Dierckx and Huyghebaert 2000). While this "wet" analytical technique is still the gold standard in protein analysis, it is time-consuming and involves the use of many dangerous chemicals both to the analyst and to the environment. Its main advantage is that the food sample used in this analytical procedure is considered large enough to be a genuine representative of the entire product. On the other hand, Dumas combustion is a more recent and faster "dry" analytical instrumental method of determining the protein content in foods and is based on the combustion of a very small sample at 900°C in the presence of oxygen. The resulting liberated nitrogen gas is analyzed in three minutes by the equipment through built-in programmed processes with the resultant value also multiplied by pre-determined conversion factors, requiring no further analysis or the use of dangerous chemicals. Both of these methods assume that all the nitrogenous compounds in the sample are proteins, but other organic molecules such as nucleotides, nucleic acids, some vitamins, and pigments (e.g., chlorophyll) also contains nitrogen, overestimating the actual protein content of the sample. Both techniques measure crude protein content, not actual protein content. While the Kjeldahl method is the internationally accepted method of protein determination for legal purposes, Dumas combustion is slowly becoming more acceptable as its accuracy and repeatability will soon be superior to that of the Kjeldahl method (Schmitter and Rihs 1989, Simonne et al. 1997).

As far back as the turn of the century, colorimetric methods for protein determination became available with procedures such as the Biuret, Lowry (original and modified), bicinchoninic acid (BCA), Bradford, and ultraviolet (UV) absorption at 280 nm (Bradford 1976). These colorimetric methods exploit the properties of specific proteins, the presence of specific amino acid functional groups, or the presence of peptide bonds. All require the extraction, isolation, and sometimes purification of the protein molecule of interest to attain an accurate absorbance reading. Considering that the nutrients in foods exist in complex matrices, these colorimetric methods are not practical for food analysis. Additionally, only a few dye-binding methods (official methods 967–12 and 975–17) have been approved for the direct determination of protein in milk (AOAC 1995).

The Biuret procedure measures the development of a purplish color produced when cupric salts in the reagent complex react with two or more peptide bonds in a protein molecule under alkaline conditions. The resultant color absorbance is measured spectroscopically at 540 nm with the color intensity (absorbance) being proportional to the protein content (Chang 1998) and with a sensitivity of 1–10 mg protein/mL. This method "measures" the peptide bonds that are common to cellular proteins, not just the presence of specific side-groups. While it is less sensitive compared to other UV methods, it is considered to be a good general protein assay for which yield is not an important issue. Likewise, the presence of interfering agents during absorbance measurement is not an issue as these substances usually absorb at lower wavelengths. While the color is stable, it should be measured within 10 minutes for best results. The main disadvantage of this method is that it consumes more material as well as it requires a 20-minute incubation period.

Over the years, further modifications to the colorimetric measurement of protein content have been made with the development of the Lowry method (Lowry et al. 1951, Peterson 1979), which combines both the Biuret reaction with the reduction of the Folin-Ciocalteu (F-C) phenol reagent (phosphomolybdic–phosphotungstic acid). The divalent cupric cations form a complex with the peptide bonds in the protein molecules, which cause them to be reduced to monovalent cations. The radical side groups of tyrosine, tryptophan, and cysteine then react with the Folin reagent, producing an unstable molybdenum/tungsten blue color when reduced under alkaline conditions. The resulting bluish color is read at both 500 nm and 750 nm wavelengths, which are highly sensitive to both high and low protein concentrations with a sensitivity of 20–100 ug, respectively. The modified Lowry method requires the absorbance measurement within 10 minutes, whereas the original Lowry method needs precise timing due to color instability. Additionally, the modified Lowry method is more sensitive to protein than the original method but less sensitive to interfering agents.

The BCA protein assay is used to determine the total protein content in a solution being similar to the Biuret, Lowry, and Bradford colorimetric protein assays. The peptide bonds in the protein molecules reduce the cupric cations in the BCA in the reagent solution to cuprous cations, a reaction that is dependent upon temperature. Afterwards, two molecules of BCA chelate the cuprous ions, changing the solution color from green to purple, which strongly absorbs at 562 nm. The amount of cupric ions reduced is dependent upon the amount of protein present, which can be measured by comparing the results with protein solutions with known concentrations. Incubating the BCA assay at temperatures of 37–60°C and for longer time periods increases the assay's sensitivity as the cuprous cations complex with the cysteine, cystine, tyrosine, and tryptophan side-chains in the amino acid residues, while minimizing the variances caused by unequal amino acid composition (Olsen and Markwell 2007).

Other methods exploit the tendency of proteins to absorb strongly in the UV spectrum, that is, 280 nm primarily due to the presence of tryptophan and tyrosine amino acid residues. Since tryptophan and tyrosine content in proteins are generally constant, the absorbance at 280 nm has been used to estimate the concentration of proteins using Beer's law. As each protein has a unique aromatic amino acid composition, the extinction coefficient (E_{280}) must be determined for each individual protein for protein content estimation.

Although these methods are appropriate for quantifying the actual amounts of protein, they do have the ability to differentiate and quantify the actual types of proteins within a mixture. The most currently used methods to detect and/or quantify specific protein components belong to the field of spectrometry,

chromatography, electrophoresis, or immunology or a combination of these methods (VanCamp and Huyghebaert 1996).

Electrophoresis is defined as the migration of ions (electrically charged molecules) in a solution through an electrical field (Smith 1998). Although several forms of this technique exist, zonal electrophoresis is perhaps the most common. Proteins are separated from a complex mixture into bands by migrating in aqueous buffers through a polyacrylamide gel with a pre-determined pore size (i.e., a solid polymer matrix). In non-denaturing/native electrophoresis, proteins are separated based on their charge, size, and hydrodynamic shape, while in denaturing polyacrylamide gel electrophoresis (PAGE), an anionic detergent sodium dodecyl sulfate (SDS) is used to separate protein subunits by size (Smith 1998). This method was used to determine the existence of differences in the protein subunits between control coffee beans and those digested by an Asian palm civet as well as between digested coffee beans from both the Asian and African civets (Marcone 2004). These protein subunits differences lead to differences in the final Maillard browning products during roasting and therefore flavor and aroma profiles. During the analysis of white and red bird's nests, Marcone determined that SDS–PAGE might be a useful analytical technique for differentiating between the more expensive red bird nest and the less expensive white bird (Marcone 2005). Additionally, this technique could possibly be used to determine if the red nest is adulterated with the less expensive white nest. Using SDS-PAGE analysis, Marcone was the first to report the presence of a 77 kDa ovotransferrin-like protein in both red and white nests, being similar in both weight and properties to ovotransferrin in chicken eggs. In isoelectric focusing, a modification of electrophoresis, proteins are separated by charge in an electrophoretic field on a gel matrix in which a pH gradient has been generated using ampholytes (molecules with both acidic and basic groups, that is, amphoteric, existing as zwitterions in specific pH ranges). The proteins migrate to the location in the pH gradient that equals the isoelectric point (pI) of the protein. Resolution is among the highest of any protein separation technique and can separate proteins with pI differences as small as 0.02 pH units (Chang 1998, Smith 1998). More recently, with the advent of capillary electrophoresis, proteins can be separated on the basis of charge or size in an electric field within a very short period of time. The primary difference between capillary electrophoresis and conventional electrophoresis (described above) is that a capillary tube is used in place of a polyacrylamide gel. The capillary tube can be used over and over again unlike a gel, which must be made and cast each time. Electrophoresis flow within the capillary also can influence separation of the proteins in capillary electrophoresis (Smith 1998).

HPLC is another extremely fast analytical technique having excellent precision and specificity as well as the proven ability to separate protein mixtures into individual components. Many different kinds of HPLC techniques exist depending on the nature of the column characteristics (chain length, porosity, etc.) and elution characteristics such as mobile phase, pH, organic modifiers, etc. In principle, proteins can be analyzed on the basis of their polarity, solubility, or size of their constituent components.

Reversed-phase chromatography was introduced in the 1950s (Howard and Martin 1950, Dierckx and Huyghebaert 2000) and has become a widely applied HPLC method for the analysis of both proteins and a wide variety of other biological compounds. Reversed-phase chromatography is generally achieved on an inert packed column, typically covalently bonded with a high density of hydrophobic functional groups such as linear hydrocarbons 4, 8, or 18 residues in length or with the relatively more polar phenyl group. Reversed-phase HPLC has proven itself useful and indispensable in the field of varietal identification. It has been shown that the processing quality of various grains depends on their physical and chemical characteristics, which are at least partially genetic in origin, and a wide range of qualities within varieties of each species exist (Osborne 1996). The selection of the appropriate cultivar is an important decision for a farmer, since it largely influences the return he receives on his investment (Dierckx and Huyghebaert 2000).

Size-exclusion chromatography separates protein molecules on the basis of their size or, more precisely, their hydrodynamic volume, and has in recent years become a very useful separation technique. Size-exclusion chromatography utilizes uniform rigid particles whose pre-determined pore size determines which protein molecules can enter and travel through the pores. Large molecules do not enter the pores of the column particles and are excluded, that is, they are eluted in the void volume of the column (i.e., elute first), whereas smaller molecules enter the column pores and therefore take longer to elute from the column. An application example of size-exclusion chromatography is the separation of soybean proteins (Oomah et al. 1994). In one study, nine peaks were eluted for soybean, corresponding to different protein size fraction, with one peak showing a high variability for the relative peak area and could serve as a possible differentiation among different cultivars. Differences, qualitatively and quantitatively, in peanut seed protein composition were detected by size-exclusion chromatography and contributed to genetic differences, processing conditions, and seed maturity. In 1990, Basha demonstrated that size-exclusion chromatography was an excellent indicator of seed maturity in peanuts as the area of one particular component (peak) was inversely proportional to increasing peanut seed maturity, which also remained unchanged toward later stages of seed maturity (Basha 1990). The peak was present in all studied cultivars, all showing a mature seed protein profile with respect to this particular protein, which was subsequently named Maturin.

LIPID ANALYSIS

Compared to most other food components, lipids are a group of relatively small, naturally occurring molecules containing carbon, hydrogen, and oxygen atoms, but with much less oxygen than carbohydrates. This large group of organic molecules includes fats, waxes, cholesterol, sterols, glycerides, phospholipids, etc. The most simplistic definition of a lipid is based on its solubility, that is, it is soluble in organic solvents (e.g., alcohol) but insoluble in water. Lipid molecules are hydrophobic, but this generality is sometimes not totally correct as some lipids are amphiphilic, that is, partially soluble in water and

partially soluble in organic solvents. Lipids are widely distributed in nature and play many important biological roles, including signaling (e.g., cholesterol), acting as structural materials in cellular membranes, and energy storage. The amphiphilic nature of some lipids gives them the ability to form cellular structures such as vesicles and liposomes within cellular aquatic environments.

Analytically, lipid insolubility in water becomes an important distinguishing characteristic that can be maximally exploited in separating lipids from other nutritional components in the food matrix such as carbohydrates and proteins (Min and Steenson 1998). Classically, lipids are divided into two groups based upon the types of bonding between the carbon atoms in the backbone, which influences the lipid's physical characteristics. Fats having a greater number of fatty acids with single carbon to carbon bonds (saturated fatty acids) cause it to solidify at 23°C (room temperature). On the other hand, the fatty acids in oils have a greater proportion of one or more double bonds between the carbon atoms (unsaturated fatty acids) and hence are liquid at room temperature. Structurally, glycerides are composed primarily of one to three fatty acids (a mixture of saturated and unsaturated fatty acids of various carbon lengths) bonded to the backbone of a glycerol molecule, forming mono-, di-, and triglycerides (the most predominant), respectively. Animal fats in the milk (from mammals), meat, and from under the skin (blubber), including pig fat, butter, ghee, and fish oil (an oil), are generally more solid than liquid at room temperature. Plant lipids tend to be liquids (i.e., they are oils) and are extracted from seeds, legumes, and nuts (e.g., peanuts, canola, corn, soybean, olive, sunflower, safflower, sesame seeds, vegetable oils, coconut, walnut, grape seed, etc.). Margarine and vegetable shortening are made from the above plant oils that are solidified through a process called hydrogenation. This method of solidifying oils increases the melting point of the original substrate but produces a type of fat called *trans* fat, whose content can be as high as 45% of the total fat content of the product. The process, however, is greatly discouraged around the world as these *trans* fats have a detrimental effect on human health (Mozaffarian et al. 2006). *Trans* fats are so detrimental to human health that the amount of *trans* fat in food has been legislated even to the point of being banned in some countries. In 2003, Denmark became the first country in the world to strictly regulate the amount of *trans* fat in foods, and since then many countries have followed this lead.

The total lipid content of a food is commonly determined using extraction methods using organic solvents, either singularly or in combinations. Unfortunately, the wide relative hydrophobicity range of lipids makes the choice of a single universal solvent for lipid extraction and quantitation nearly impossible (Min and Steenson 1998). In addition to various solvents that can be used in the solvent extraction methods, non-solvent wet extraction methods and other instrumental methods also exist, which utilize the chemical and physical properties of lipids for content determination.

One of the most frequent and easiest methods to determine the crude fat content in a food sample is the Soxhlet method, a semicontinuous extraction method using relatively small amounts of various organic solvents. In this method, the solid food sample (usually, dried and pulverized) is placed in a thimble in the chamber and is completely submerged in the hot solvent for 10 minutes or more before both the extracted lipid and solvent are siphoned back into a boiling flask reservoir. The whole process is repeated numerous times until all the fat is removed, which usually requires at least two hours. The lipid content is determined by measuring either the weight loss of the sample in the thimble or by the weight gain of the flask reservoir. The main advantage of this method is that it is relatively quick and specific for fat as other food components such as proteins and carbohydrates are water soluble. Some preparation of the sample, such as drying, pulverizing, and weighing, may be needed to increase the extraction efficiency as extraction rates are influenced by the size of the food particles in the sample, food matrix, etc. If the fat component needs to be removed from the sample before further analysis, the method also allows for the sample in the thimble to remain intact without destruction.

Another excellent method for total fat determination is supercritical fluid extraction. In this method, a compressed gas (e.g., CO_2) is brought to a specific pressure–temperature point that allows it to attain supercritical solvent properties for the selective extraction of a lipid from a food matrix by diffusing through it (Mohamed and Mansoori 2002). This method permits the selective extraction of lipids, while other lipids remain in the food matrix (Min and Steenson 1998). The dissolved fat is then separated from the compressed/liquefied gas by reducing the pressure, and the precipitated lipid is then quantified as a percent lipid by weight (Min and Steenson 1998).

A third often used method for total lipid quantitation is infrared, which is based on the absorption of infrared energy by fat at a wavelength of 5.73 um (Min and Steenson 1998). In general, there is a direct proportional relationship between the amount of energy absorbed at this wavelength and the lipid content in the material. Near-infrared spectroscopy has been successfully used to measure the lipid content of various oilseeds, cereals, and meats. The added advantage is that it maintains the integrity of the sample, which is in contrast to the other previously reviewed methods.

Although these three cited methods are appropriate to quantify the actual amounts of lipids in a given sample, they are not able to determine the types of fatty acids within a lipid sample. In order to determine the composition of the lipid, GC offers the ability to characterize these lipids in terms of their fatty acid composition (Pike 1998). The first step is to isolate all mono-, di-, and triglycerides needed if a mixture exists usually by simple adsorption chromatography on silica or by using a one- or two-phase solvent–water extraction method. The isolated glycerides are then hydrolyzed to release the individual fatty acids and subsequently converted to their ester form, that is, the glycerides are saponified and the liberated fatty acids are esterified to form fatty acid methyl esters, that is, they are derivatized. The method of derivatization is dependent upon the food matrix, and the choice is an important consideration as some methods can produce undesired artifacts. The fatty acids are now volatile and can be separated chromatographically using various gases, various packed or capillary columns, and a variety of temperature–time gradients.

The separation of the actual mono-, di-, and triglycerides is usually much more problematic than determining their individual fatty acid constituents or building blocks. Although GC has also been used for this purpose, such methods result in insufficient information about the complete triglyceride composition in a complex mixture. Such analyses are important for the edible oil industry for process and product quality control purposes as well as for the understanding of triglyceride biosynthesis and deposition in plant and animal cells (Marini 2000).

Using HPLC analysis, Plattner et al. (1977) were able to establish that, under isocratic conditions, the logarithm of the elution volume of a triacylglycerol (TAG) was directly proportional to the total number of carbon atoms (CN) and inversely proportional to the total number of double bonds (X) in the three fatty acyl chains (Marini 2000). The elution behavior is controlled by the equivalent carbon number (ECN) or a TAG, which may be defined as $ECN = CN − X.n$ where n is the factor for double bond contribution, normally close to 2.

The IUPAC Commission on Oils, Fats, and Derivatives undertook the development of a method for the determination of triglycerides in vegetable oils by liquid chromatography. Materials studied included various oils extracted from plant materials such as soybeans, almonds, sunflowers, olives, canola, and blends of palm and sunflower oils, and almond and sunflower oils (Fireston 1994, Marini 2000). The method for the determination of triglycerides (by partition numbers) in vegetable oils by liquid chromatography was adopted by AOAC International as an official IUPAC-AOC-AOAC method. In this method, triglycerides in vegetable oils are separated according to their ECN by reversed-phase HPLC and detected by differential refractometry. Elution order is determined by calculating the ECNs, $ECN = s$ and $CN − 2_n$, where CN is the carbon number and n is the number of double bonds (Marini 2000).

CARBOHYDRATE ANALYSIS

Carbohydrates comprise approximately 70% of the total caloric intake in many parts of the world, being the major source of energy for most of the world (BeMiller and Low 1998). In foods, these macromolecules have various important roles, including imparting important physical properties to foods such as sensory characteristics and viscosity.

The vast majority of carbohydrates are of plant origin mostly in the form of polysaccharides (BeMiller and Low 1998). Most of these polysaccharides are non-digestible by humans, the only digestible polysaccharide being the starch. The non-digestible polysaccharides are divided into two groups, soluble and insoluble, forming what is referred to as dietary fiber. Each of these two groups has specific functions not only in the plant tissues but also in human and animal digestive systems, subsequently influencing the health of the entire organism.

For many years, the total carbohydrate content was determined by exploiting their tendency to condense with phenolic-type compounds, including pheno, orcinol, resorcinol, napthoresorcinol, and α-naphthol (BeMiller and Low 1998). The most widely used condensation reaction was with phenol, which was used to determine virtually all types of carbohydrates including mono-, di-, oligo-, and polysaccharides. The analytic method is a rapid, simple, and specific determination for carbohydrates. After reaction with phenol in acidic conditions in the presence of heat, a stable color is produced, which is read spectrophotometrically. A standard curve is usually prepared with a carbohydrate similar to the one being measured.

Although the above method was, and is still, used to quantify the total amount of carbohydrate in a given sample, it does not offer the ability to determine the actual types of individual carbohydrates in a sample. Earlier methods such as paper chromatography, open column chromatography, and thin-layer chromatography have largely been replaced by either HPLC and/or GC (Peris-Tortajada 2000). GC has become established as an important method in carbohydrate determinations since the early 1960s (Sweeley et al. 1963, Peris-Tortajada 2000) and several unique applications have since then been reported (El Rassi 1995).

For GC analysis, carbohydrates must first be converted into volatile derivatives, the most common derivatization agent being trimethylsilyl (TMS). In this analytic technique, the aldonic acid forms of carbohydrates are converted into their TMS ethers, which are then injected directly into the chromatograph having a flame ionization detector. Temperature programming is utilized to maximally optimize the separation and identification of individual components. Unlike GC, HPLC analysis of carbohydrates requires no prior derivatization of carbohydrates and gives both qualitative (identification of peaks) and quantitative information of complex mixtures of carbohydrates. HPLC is an excellent method for the separation and analysis of a wide variety of carbohydrates ranging from the smaller and relatively structurally simpler monosaccharides to the larger and more structurally complex oligosaccharides. For the analysis of the larger polysaccharides and oligosaccharides, a hydrolysis step is needed prior to chromatographic analysis. A variety of different columns can be used with bonded amino phases used to separate carbohydrates with molecular weights up to about 2500 kDa depending upon carbohydrate composition and their specific solubility properties (Peris-Tortajada 2000). The elution order on amine-bonded stationary phases is usually monosaccharide and sugar alcohols followed by disaccharides and oligosaccharides. Such columns have been successfully used to analyze carbohydrates in fruits and vegetables as well as processed foods such as cakes, confectionaries, beverages, and breakfast cereals (BeMiller and Low 1998). With larger polysaccharides, gel filtration becomes the preferred chromatographic technique as found in the literature. Gel filtration media such as Sephadex and Bio-Gel have successfully been used to characterize polysaccharides according to molecular weights.

MINERAL ANALYSIS

A (dietary) mineral is any inorganic chemical element in its ionic form, excluding the four elements, namely carbon, nitrogen, oxygen, and hydrogen. These minerals are important as they are required for a wide range of physiological functions, including energy generation, enzyme production, providing structure (skeleton), circulation fluids (blood), movement (muscle and

nerve function), digestion (stomach acid production), and hormone production (thyroxine), just to name a few. It has been estimated that 98% of the calcium and 80% of the phosphorous in the human body are bound-up within the skeleton (Hendriks 1998). Those that are directly involved in physiological function (such as in muscle contraction) include sodium, calcium, potassium, and magnesium.

Most minerals (calcium, chloride, cobalt, copper, iodine, iron, magnesium, manganese, molybdenum, nickel, phosphorous, potassium, selenium, sodium, sulfur, and zinc) are considered to be essential nutrients in the classical sense as they are needed for physiological functions and must be obtained from dietary sources. Additionally, there is a much smaller group of minerals (arsenic, boron, chromium, and silicon) that have a speculated role in human health, but their roles have not been conclusively established, yet. Some minerals are referred to as macro-minerals as they are required by humans in amounts greater than 100 mg per day, including sodium, potassium, magnesium, phosphorous, calcium, chlorine, and sulfur. A further ten minerals are classified as micro or trace minerals as they are required in milligram quantities per day, including silica, selenium, fluoride, molybdenum, manganese, chromium, copper, zinc, iodine, and iron (Hendriks 1998). In humans, both the macro- and micro- minerals can contribute to disease development in either excessive or deficient amounts.

Although many minerals are naturally found in most raw food sources, some are added to foods during processing for different purposes. An example of this is the addition of salt (sodium) during processing to decrease water activity and to act as a preservative, for example, pickles and cheddar cheese (Hendriks 1998). It should also be noted that food processing can also cause a decrease in the mineral content, for example, the milling of wheat removes the mineral-rich bran layer. During the actual washing and blanching of various foods, important minerals are often lost in the water. It can therefore be concluded that accurate and specific methods for mineral determination are in fact important for nutritional purposes as well as in properly processing food products for both human and animal consumption.

Many countries have laws specifying which minerals must be added to specific foods in legally specified amounts and forms. Iron is added to fortify white flour and various other minerals, including calcium, iron, and zinc, are added to various breakfast cereals. In North America, salt itself is fortified with iodine to inhibit the development of goiter. Additionally, minerals are affected by legal considerations. A food's nutrition label must declare the mineral content of the food in certain cases, such as baked goods. In some countries such as the United States, the link between a mineral in specified amounts and its health effects is permitted, whereas in countries such as Canada, legally predetermined statements may be put on the food product packaging.

To determine the total mineral content in a food, the ashing procedure is usually the method of choice. The word "ash" refers to the inorganic residue that remains after either ignition or, in some cases, complete oxidation of the organic material (Harbers 1998). Ashing can be divided into three main types—dry ashing (most commonly used), wet ashing (oxidation) for samples with a high fat content such as meat products or for preparation for elemental analysis, and plasma ashing (low temperature) when volatile elemental analysis is conducted.

In dry ashing, food samples are incinerated in a muffle furnace at temperatures of 500–600°C. During this process, most minerals are converted to either oxides, phosphates, sulfates, chlorides, or silicates. Unfortunately, some minerals such as mercury, iron, selenium, and lead may be partially volatized using this high-temperature procedure. Wet ashing involves the use of various acids that oxidize the organic materials while the minerals are subsequently solubilized without volatilization. Nitric or perchloric acids that are often used along with reagent blanks are carried throughout the entire procedure and then subtracted from sample results. In the low-temperature plasma ashing, the food sample is treated in a similar manner as in dry ashing but under a partial vacuum, with samples being oxidized by nascent oxygen formed by an electromagnetic field.

Although the above three ashing methods have been proven to be adequate for quantifying the total amount of minerals in a sample, they do not possess the ability to differentiate nor to quantify the actual mineral elements in a food sample. Atomic absorption spectrometers became widely used in the 1960s and 1970s and paved the way for measuring the presence and trace amounts of minerals in various biological samples (Miller 1998). Essentially, atomic absorption spectroscopy is an analytical technique based on the absorption of UV or visible radiation by free atoms in the gaseous state. However, the sample must first be ashed and then diluted in weak acid. The solution is then atomized into a flame. According to Beer's law, the absorption is directly related to the concentration of a particular element in the sample.

Atomic emission spectroscopy differs from atomic absorption spectroscopy in that the source of the radiation is in fact the excited atoms or ions in the sample rather than an external source has in part taken over. Atomic emission spectroscopy does have the advantages with regard to sensitivity, interference, and multi-element analysis (Miller 1998).

Recently, the use of ion-selective electrodes has made online testing of the mineral composition of samples a reality. In fact, many different electrodes have been developed to directly measure various anions and cations, such as calcium, bromide, fluoride, chloride, potassium, sulfide, and sodium (Hendriks 1998). Typically, levels as low as 0.023 pm can be measured. When working with ion-selective electrodes, it is common procedure to establish a calibration curve.

VITAMIN ANALYSIS

Vitamins are low-molecular weight organic compounds obtained from external sources in the diet and are critical for normal physiological and metabolic functions (Russell 2000). Vitamins are divided into two groups based on liquid solubility, that is, those that are water soluble (B vitamins and vitamin C) and those that are fat soluble (vitamins A, D, E, and K). Since the vast majority of vitamins cannot be synthesized by humans, they must be obtained either from food sources or from manufactured dietary supplements.

Vitamin analysis of foods are completed for numerous reasons, including regulatory compliance, nutrient labeling, investigating the changes in vitamin content attributable to food processing, packaging, and storage (Ball 2000). As such, numerous analytical methods have been developed to determine their levels during processing and in their final product.

The scientific literature contains numerous analytical methods for the quantitation of water-soluble vitamins, including several bioassays, calorimetric, and fluorescent assays, all of which have been proven to be accurate, specific, and reproducible for both raw and processed food products (Eitenmiller et al. 1998). By far, HPLC has become the most popular technique for quantifying water-soluble vitamins, and the scientific literature contains an abundance of HPLC-based methodologies (Russell 2000). In general, it is the nonvolatile and hydrophilic natures of these vitamins that make them excellent candidates for reversed-phase HPLC analysis (Russell 1998). The ability to automate using autosamplers and robotics makes HPLC an increasingly popular technique. Since the vast majority of vitamins occur in trace amounts in foods, detection and sensitivity are critical considerations. Although UV absorbance is the most common detection method, both fluorescence and electrochemical detection are also used in specific cases. Refractive index detection is seldom used for vitamin detection due to its inherent lack of specificity and sensitivity.

During the 1960s, GC with packed columns was widely used for determining the presence and concentrations of various fat-soluble vitamins, especially vitamins D and E. Unfortunately, additional preliminary techniques such as thin-layer chromatography and open-column techniques were still necessary for the preliminary separation of the vitamins, followed by derivatization to increase their thermal stability and volatility (Ball 2000). More recently, the development of fused-silica open tubular capillary columns has revived the used of GC, leading to a number of recent applications for the determination of fat-soluble vitamins, especially vitamin E (Marks 1988, Ulberth 1991, Kmostak and Kurtz 1993, Mariani and Bellan 1996). Even so, HPLC is also the method of choice for the fat-soluble vitamins in foods (Ball 1998). The main advantage of this technique is that the vitamins need not be derivatized, and the method allows for both greater separation and detection selectivity. Various analytical HPLC methods have been introduced for the first time in the 1995 edition of the Official Methods of Analysis of AOAC International, including vitamin A in milk (AOAC 992.04 1995) and vitamin A (AOAC 992.26 1995), vitamin E (AOAC 992.03 1995), and vitamin K (AOAC 992.27 1995) in various milk-based infant formulas (Ball 1998).

At the present time, there are no universally recognized standardized methods that can be applied to all food types for determining the presence, amount, or identity of the fat-soluble vitamins (Ball 1998).

PIGMENT ANALYSIS

The color of food is a very important sensory characteristic as it is often used as an indicator of both food quality and safety (Schwartz 1998). A vast number of natural and synthetic pigments are obtained from both plant and animal sources as well as are developed during processes, for example, carmelization and Maillard browning reactions. The majority of the naturally occurring pigments in foods are divided into five major classes, four of which are found in plant tissues while the fifth is found in animal tissues (Schwartz 1998). Of those found in plants, two are lipid soluble, that is, the chlorophylls (green) and the carotenoids (yellow, orange, and red), with the other two are water soluble, that is, anthocyanins (color usually depending upon pH, red in acidic conditions and blue in basic) and betalains (yellow or red indole-derived). Carotenoids are found in both plant (e.g., carotenoids (carrots), lycopene (tomatoes)) and animal tissues (e.g., milk, egg yolk), but in animals they are derived from dietary sources, for example, the yellow color in milk/egg yolk is due to the consumption of green plants during pasture feeding with various grasses, clovers, etc. (Schwartz 1998), not from biosynthesis in the animal itself.

Several analytical methods exist for the analysis of chlorophylls in a wide variety of foods. Early spectrophotometric methods permitted the quantification of both chlorophyll a and b by measuring the absorbance maxima of both chlorophyll types. Unfortunately, only fresh plant material could be assayed as no pheophytin could be determined. This became the basis for the AOAC International spectrophotometric procedure (Method 942.04), which provides results for total chlorophyll content as well as for chlorophyll a and b quantitation.

Schwartz et al. (1981) described a simple reversed-phase HPLC method for the analysis of chlorophyll and their derivatives in fresh and processed plant tissues. This method simplified the determination of chemical alterations in chlorophyll during food processing and allowed for the determination of both pheophytins and pyropheophytins.

Numerous HPLC methods have been developed for carotenoid analysis, specifically for the separation of the different carotenoids found in fruits and vegetables (Bureau and Bushway 1986). Both normal and reversed-phase methods have been used with the reversed-phase methods predominating (Schwartz 1998). Reversed-phase chromatography on C-18 columns using isocratic elution procedures with mixtures of methanol and acetonitrile containing ethyl acetate, chloroform or tetrahydrofuran have been determined to be satisfactory (Schwartz 1998). Carotenoids are usually detected in wavelengths ranging from 430 nm to 480 nm. Since β-carotene in hexane has an absorption maximum at 453 nm, many methods have detected a wide variety of carotenoids in this region (Schwartz 1998).

Measurements of the water-soluble but pH color-dependent anthocyanins (red, purple, or blue) have been performed by determining absorbance of diluted samples acidified to approximately pH 1.0 at wavelengths between 510 nm and 540 nm. Unfortunately, absorbance measurements of anthocyanins provide only total quantification and any further information about the presence and amounts of various other individual anthocyanins must be performed by other methods. HPLC methods using reversed-phase methods employing C-18 columns have been the methods of choice as the anthocyanins are water soluble. Mixtures of water, acetic, formic, or phosphoric acids usually are used as part of the mobile phase.

Charged pigments such as the red-violet colored betalains can be separated by electrophoresis, but reversed-phase HPLC provides more rapid resolution and quantification (Cai et al. 2005). Betalains have been separated on reversed-phase columns using various ion-paring or ion-suppression techniques (Schwartz and Von Elbe 1980, Huang and Von Elbe 1985). This procedure allows for more interaction of the individual betalains molecules with the stationary phase and better separation between individual components.

ANTIOXIDANTS

An increasingly important group of nonnutritive food components are the antioxidants, a large group of biologically active chemicals in plant and animal tissues usually in relatively small concentrations (compared to their substrates; Halliwell and Gutteridge 1995). As the name implies, an antioxidant mitigates/prevents the oxidation of other molecules that are more easily oxidized, for example, vitamin E in oil prevents the auto-oxidation of lipids, and antioxidants are "strong" reducing agents. Antioxidants can accomplish this task via three possible mechanisms. The first is to prevent free-radical generating reactions (oxidation reactions) from occurring, the second involves inhibiting/scavenging for reactive species, and the third involves the chelation/sequestering of metals that can act as catalysts. Whichever pathway, antioxidants "protect" susceptible molecules such as membrane lipids from being oxidized, thereby maintaining their structural and functional integrity (Dilis and Trichopoulou 2010).

These naturally occurring antioxidants consist of vitamins, enzymes (proteins), minerals, pigments, organic acids, and hormones (Prior et al. 2005), which include vitamins C (ascorbic acid) and E and its isomers (α-tocopherol and tocotrienols); selenium and manganese (minerals); α-carotene, β-carotene, lutein, lycopene, etc. (carotenoid terpenoids); catalases, glutathione (a thiol), peroxidases, reductases, and superoxide dismutases (enzymes); flavones, flavenols, flavanones, flavanols and their polymers, isoflavone phytoestrogens, stilbenoids, and anthocyanins (all polyphenolic flavenoids); chlorogenic acid, cinnamic acid (and its derivatives), gallic acid, etc. (all phenolic acids and their esters); xanthones and eugenol (non-flavenoid phenolics); lignin, bilirubin, citric, oxalic, phytic acids, etc. (organic molecules); and melatonin, angiotensin, and estrogen (hormones) (Sies 1997, Prior et al. 2005, Dilis and Trichopoulou 2010).

Chemically speaking, an oxidation reaction involves the transfer of one or more electron(s) from one molecule to another (a redox reaction), thereby creating a charged molecule/molecular fragment called a free radical (essentially, an ion with positive or negative charge), which can further promote subsequent reactions, leading to the generation of more free radicals. By their very nature, free radicals are very reactive as they have an unpaired electron in their outer shell configuration and, in an attempt to reach stability, they donate/receive electrons to/from other molecules such as lipids, proteins, and genetic material (DNA). This interaction damages these more oxidizable molecules, which impairs their functions. Antioxidants can either donate hydrogen atoms or donate/receive electrons to/from free radicals. While the "intervention" of the antioxidants causes the antioxidants to become radicals themselves, these radicals are more stable, eventually returning to their original state.

The human body produces free radicals through normal metabolic processes such as aerobic respiration, while inflammation and disease processes, exercise, exposure to exogenous environmental chemicals, tobacco (including tobacco smoke), sun-exposure (radiation), and chemicals (cleaning products and cosmetics) are also sources of free radicals (Freeman and Capro 1982, Southorn and Powis 1988). The most abundant group of free radicals produced in the human body involve oxygen, and they are often referred to reactive oxygen species (ROS), a group of peroxyl radicals including superoxide anions (O_2^-), hydroxyl radicals (OH·), singlet oxygen radicals ($^1O_2$·), hydrogen peroxide (H_2O_2), and ozone (O_3). Other free radical producers/enablers include iron and copper (transition metals acting as catalysts), which promote the production of more aggressive free radicals (Valko et al. 2005, Apak et al. 2007) as well as nitric oxide. Biologically, some of the free radicals have critical biological functions, for example, some of the ROS species are used by the immune system to attack and kill pathogens and nitric oxide is involved in cell (redox) signaling (Somogyi et al. 2007).

A diet high in refined sugars and grains, foods cured with nitrites, pesticides, and hydrogenated vegetable oils coupled with decreased consumption of whole grains, fruits, vegetables, and non-/minimally processed foods, and non-healthy lifestyle generates more free radicals compared to a totally opposite diet (Bruce et al. 2000). It has been hypothesized that free-radical generating diets can lead to oxidative stress, an unbalanced state characterized by increased free-radical concentrations coupled with decreased antioxidant concentrations. This state has been implicated in the aging process as well as in many diseases/conditions such as Alzheimer's disease, Parkinson's disease, cardiovascular disease (including heart attack and stroke), various cancers, cellular DNA damage, rheumatoid arthritis, and cataracts (Etherton et al. 2002, Stanner et al. 2004, Shenkin 2006, Nunomura et al. 2006). Epidemiological studies have suggested the benefits of a high antioxidant diet, but clinical trials have provided mixed results (Pérez et al. 2009, Dilis and Trichopoulou 2010). This would seem to suggest that antioxidants may only be partially responsible or work in synergism with other biologically active molecules (Cherubini et al. 2005, Seeram et al. 2005). However, some clinical investigations have demonstrated that antioxidants can also act as pro-oxidants in some diseases (Bjelakovic et al. 2007). Because of their possible varied functionalities in disease prevention, mitigation, or even treatment, the food industry is very much interested in promoting the presence of either naturally occurring or added antioxidants in their products. Pharmaceutical companies too are interested in antioxidants through the creation and marketing of various dietary supplements or pharmaceutical drugs for the treatment of diseases.

Currently, antioxidant assays are divided into two groups, the division being based on the underlying reaction mechanisms, hydrogen atom transfer (HAT) and electron transfer (ET; Prior et al. 2005), which can work in tandem in some assays. Details of

these two reaction mechanisms, the descriptions of the various assays, and their comparisons have been published extensively over the past 20 years (Halliwell 1994, Prior and Cao 1999, Huang et al. 2005, Prior et al. 2005, Apak et al. 2007, Phipps et al. 2007, Moon and Shibamoto 2009). HAT mechanisms measure the ability of antioxidants to quench free radicals by donating a hydrogen atom. This ability is critical as the transfer of a hydrogen atom is a critical step in preventing/stopping radical chain reactions (Huang et al. 2005). HAT-based assays uses a synthetic free-radical generator, an oxidizable probe (usually fluorescent), and the antioxidant (Huang et al. 2005), monitoring the competitive reaction kinetics with final quantification derived from kinetic curves. ET-based assays, on the other hand, are colorimetric assays that measure the change in color as the oxidant is reduced. The mechanism itself involves only one redox reaction, with the result being a quantifiable measurement of the antioxidant's reducing capacity (Huang et al. 2005).

Common HAT assays include oxygen radical absorbance capacity (ORAC), total radical trapping antioxidant parameter (TRAP; and some of its variants), and total oxidant scavenging capacity (TOSC). ORAC assays are the most widely used in research, clinical, and food laboratories for antioxidant quantification. This assay represents the classical antioxidant mechanism by hydrogen transfer and can measure both in vivo hydrophilic and lipophilic antioxidants, the latter by using selective combinations of solvents with relatively small polarities. It is widely used to measure the antioxidant capacity (AOC) of food samples ranging from pure compounds (e.g., melatonin) to complex matrices such as fruits and vegetables (Prior and Cao 1999). Peroxyl radicals generated with an azo-initiator compound are added to microplate wells along with a fluorescent probe and the extracted antioxidant. As the reaction progresses, fewer and fewer of the antioxidants are available to donate hydrogen atoms to the peroxyl radicals, which lead to radicals combining with the fluorescent probe and forming a nonfluorescent molecule. The reaction is quantified using a fluorometer over a period of 35 minutes, which is the time taken for the free radical action to complete. The length of the ORAC assay also minimizes the possibility of underestimating the total antioxidant concentration as some secondary antioxidant products have slower reaction kinetics. The effectiveness of the antioxidant is calculated from the area between two curves generated when the assay is performed with a sample and a blank, thereby combining both length of inhibition and percentage inhibition into a single quantity (Cao et al. 1995), with the results expressed as Trolox (a vitamin E analogue) equivalents, that is, μM Trolox equivalents (TE) per gram. One of the great advantages of the ORAC method is other radical sources can be used (Prior et al. 2005) and has also been developed for automation, which reduces the traditional time-consuming analysis as well as human reaction time and other sources of human error. In 2007, the United States Department of Agriculture published a report entitled "Oxygen Radical Absorbance Capacity (ORAC) of Selected Foods—2007" (USDA 2007), which lists the ORAC values (hydrophilic and lipophilic) as well as ferric-ion reducing antioxidant power (FRAP) and Trolox equivalence antioxidant capacity (TEAC) assays for 59 different foods in the American diet.

The second HAT mechanism is the TRAP assay, which measures the ability of an antioxidant to interfere with the reaction between a hydrophilic peroxyl radical generator such as 2,2′-azobis(2-amidinopropane) dihydrocholride and a target probe. The effectiveness of the antioxidant to interfere in this reaction is measured by the consumption of oxygen during the reaction with the oxidation of the probe followed optically or by fluorescence (Prior et al. 2005). In the initial lag phase, the oxidation is inhibited by the antioxidants and is compared to the internal Trolox standard. TRAP values are reported as a lag time or reaction time compared to the corresponding times for Trolox (Prior et al. 2005). The TRAP antioxidant assay is most useful for measuring serum or plasma AOC, that is, in vivo nonenzymatic antioxidants such as glutathione and nutritive antioxidant (pro-) vitamins such as vitamin A (β-carotene), C (ascorbic acid), and E (α-tocopherol). This assay is also sensitive to all antioxidants that are capable of breaking the reaction generating peroxyl radicals. The major disadvantage is that the assay assumes all antioxidants have a lag phase, but this is untrue. The total AOC is underestimated as the antioxidant value contributed after the lag phase (if one is present) is not taken into account and also assumes that the lag phase is proportional to AOC.

The third assay to measure the HAT mechanism is TOSC, which quantifies the absorbance capacity of three oxidants—hydroxyl radicals, peroxyl radicals, and peroxynitrite—thereby making it applicable to evaluate antioxidants from different biological sources (Prior et al. 2005). The substrate is α-keto-γ-methiolbutyric acid, which forms ethylene when oxidized and is measured over time by headspace analysis by GC. The AOC of the antioxidant is determined by its ability to inhibit ethylene formation. Like the ORAC, this assay is determined by the area between the curve generated by the sample and that of the control. The major advantage is that it can quantify the effects of three common radicals of interest, but it is time-consuming as the GC analysis can take 300 minutes, requiring multiple injections of ethylene that has been collected from a single sample into the GC. Additionally, the percentage antioxidant inhibition and its concentration are not linear, which requires a graph generated by various dilution factors with the DT_{50} calculated by the first derivation of this dose–response curve.

The only major assays measuring ET mechanisms (reducing power) is the FRAP, which was initially developed to measure the OAC of plasma but has been adapted for samples of botanical origins (Prior et al. 2005). The low pH reaction measures the reduction of ferric 2,4,6-tripyridyl-s-triazine by antioxidants in a redox-linked colorimetric method with a redox potential < 0.7 V (Phipps et al. 2007). The bright blue color caused by the presence of the ferrous ion is measured spectrophotometrically at 593 nm. The major advantage is that the assay is inexpensive, the results are producible, and the assay is short, leading to automated or semi-automated high throughput. The major drawback with the FRAP assay is that a chemical reductant and a biological antioxidant are treated identically, but the assay neither directly use a pro-oxidant nor use an oxidizable substrate (Prior and Cao 1999). The ferric ion (Fe^{3+}) is not necessarily a pro-oxidant such as the ferrous ion (Fe^{2+}) that reacts with hydrogen peroxide (a peroxyl free radical). Additionally,

neither ion is able to cause direct oxidative damage to easily oxidized biological molecules such as lipids, proteins, and DNA. Additionally, the assay is unable to measure the effects of antioxidants that act strictly on HAT (mechanisms such as thiols and proteins), leading to underestimation of serum AOC but may be useful in combination with other assays to differentiate between antioxidant mechanisms.

Both the TEAC and other ABTS (2,2′-azinobis[3-ethylbenzothiazoline-6-sulfonic acid] di-ammonium salt) assay as well as DPPH assay (1,1-diphenyl-2-picryl-hydrazyl) use indicator radicals that may be neutralized by either HAT or ET mechanisms. In the TEAC (and its related assays), the long life anion ABTS molecule is oxidized to its cation radical form (ABTS·$^{+}$) by peroxyl radicals, forming an intensely colored liquid. The AOC is determined by the ability of the antioxidant to decrease the color by reacting with the cation, which is measured with a spectrophotometer at 415, 645, 734, and 815 nm (Prior et al. 2005). As with ORAC, the results are expressed in TE. This assay offers advantages over some of the other assays described previously. Its major advantage is that antioxidant mechanisms as influenced by pH can be studied over a wide pH range. Additionally, the generation cation radical is soluble in both polar and nonpolar solvents and is not affected by ionic strength. While it measures both hydrophilic and lipophilic antioxidants, it does tend to favor the hydrophilic species, but this can be overcome by using buffered media or partitioning the antioxidants between hydrophilic and lipophilic solvents. In terms of effort, the assay is short (30 minutes) as the antioxidants react rapidly with the generated cation radical The major objection to this assay is that the ABTS radical is not found in mammalian tissues and thus represents a synthetic radical source, but any molecule, such as phenolic compounds, that have low redox potentials can react with ABTS^{+} (Prior et al. 2005). As with some of the other assays, TEAC may have long initial lag phases, and the assay may not go to completion before stopping itself, resulting in OAC underestimation.

The theory of the DPPH assay is based on the ability of the antioxidants to reduce it to its radical form, DPPH·, a stable nitrogen radical producing a deep purple color with the decrease in color monitored by absorbance at 515 nm or by electron spin resonance. The results are reported as EC$_{50}$, which measures a 50% decrease in the DPPH· concentration, which is proportional to the antioxidant concentration (Prior et al. 2005). This assay is also quick and only requires the use of a spectrophotometer, but results are difficult to interpret as compounds such as the carotenoids also absorb maximally at 515 nm. The major disadvantage is that DPPH acts both as the radical probe and as the oxidant. As a radical, DPPH is not involved in lipid peroxidation. Many antioxidants react with peroxyl radicals, but DPPH may be inaccessible to the antioxidants or may interact with them very slowly.

The F-C assay, aka total phenolics assay, is a measure of the AOC of the total phenolic content of a (food) sample. Since its development in 1927 for tyrosine analysis, it has been developed and improved to measure the AOC of all the phenolic molecules of a sample (Singleton and Rossi 1965). These phenolic compounds are oxidized by a molybdotungsto-phosphoric heteropolyanion reagent with the reduced phenols, producing a colored product that is measured maximally at 765 nm. While the method is simple, it has a number of drawbacks. The method must be followed exactly and explicitly to minimize variability and erratic results. The assay suffers from a large number of interfering but naturally occurring substances such as fructose, ascorbic acid, aromatic amino acids, and other compounds that are listed by Prior et al. (2005). However, this limitation was overcome in a study on the phenolic content of urine by using solid-phase extraction to remove the water-soluble compounds from the sample (Roura et al. 2006). It should also be taken into consideration that the phenolic composition in different samples would react differently as is demonstrated by the F-C assay of different foods (cf. Figure 7, Prior et al. 2005).

For analytical chemists, it becomes increasingly important to understand the composition of the food matrix as the different antioxidant assays may not be identical in their underlying mechanisms. Additionally, the results must also take into account the effect of geography, soils, climatic conditions, variety, seasonality, transportation, processing, etc. of a particular food, as these can influence resulting antioxidant values (Dewanto et al. 2002, Tsao et al. 2006, Xu and Chang 2008).

In light of the different underlying reaction mechanisms, the different antioxidants, their target free radicals, and their environmental conditions, the food matrix, etc., the dilemma becomes apparent as to which assay to choose as much has to be taken into consideration. Extraction methodologies, detection, quantification, measuring the effectiveness of the vast array of antioxidants against their target free radicals, as well as interpreting the results (Prior et al. 2005) are just some considerations. As can also be deduced, the different assays have their advantages/disadvantages, and the result of one cannot be compared to the results of another. None of the assays can be considered as measurements of total antioxidant activity as antioxidants are indeed varied.

As a result of all these challenges and concerns, 144 scientists met at the First International Congress on Antioxidant Methods in 2004 to standardize these issues across all laboratories worldwide, with all resultant works are to be published in *The Journal of Agricultural Food Chemistry* (Prior et al. 2005). We look forward to the fruit of this enormous and invaluable effort.

GAS CHROMATOGRAPHY—MASS SPECTROSCOPY

GC–MS is a common and powerful analytical technique used in both agricultural and food industries, which combines the features of both GC and MS. Developed in the 1950s by Roland Gohike and Fred McLaffert, GC–MS first separates the prepared sample (containing a mixture of compounds) into separate and distinct compounds (by GC) and then positively identifies and quantifies these compounds based on their ion fragment pattern (by MS). This approach is advantageous as it identifies a molecule by both its unique retention time as well as its unique fragmentation pattern. The results are graphically illustrated in a mass spectrum graph that yields both qualitative and quantitative information about the substance(s) of interest.

GC separates (partitions) and analyzes molecules of interest such as lipids and carbohydrates, which can be volatilized (naturally or chemically) without decomposition or creation of chemical artifacts. The volatilized compounds are injected into the GC, vaporized, and carried through a column by an inert gas, where they differentially interact with the inner lining of the column. Their rate of release from the column lining is based on their attraction with the column lining, and after being released, they are carried to the detector that electronically records the amount of time each substance has taken to travel through the column. MS, on the other hand, determines the elemental composition of a sample, such as the gaseous effluent from a gas chromatograph. Molecules are ionized, creating both charged molecules as well as their various fragments. These charged substances are accelerated through an electromagnetic field that filters the ions based on a predetermined mass size. The ions are then counted by a detector that sends the information to a computer, which generates a "graph" showing both the number of the various ion fragments with their different masses and their relative amounts. Each chemical has a specific fragmentation pattern, just like a human fingerprint or iris pattern.

GC–MS is used for substances that are thermally stable (up to 300°C) and relatively volatile at temperatures less than 300°C, whereas liquid chromatography–MS (LC–MS or HPLC–MS) is used for chemicals that are not volatile and/or degrade at temperatures above room temperatures. Nonvolatile chemicals can be made volatile with derivatizing agents, but not all derivatizing agents and solvents are compatible with various components of GC or HPLC equipment. Both GC–MS and LC–MS provide the much-needed sensitivity than either equipment used alone. Conventional tests such as Kjeldahl or Dumas can determine if a sample contains any substances that can be categorized as proteins, carbohydrate, lipid, etc., but these single methods are not able to specifically identify the substance of interest. The main advantage of using these two analytical tools in tandem (GC–MS) is that together they positively identify (confirm) the presence of any chemical in a sample with no false positive results even to levels as low as 5 ppb (Tareke et al. 2002). Using the analogy of a puzzle, single tests such as Kjeldahl or Dumas provide one piece to the puzzle, whereas GC–MS provides the entire picture. Both single and tandem analytical approaches are valid but before starting any analysis, one has to determine what information is needed and which analytical test(s) would best provide that information to meet the criteria of identification, accuracy, and sensitivity.

Currently, food applications of GC–MS is primarily limited to detect the presence of contaminants such as pesticides, insecticides, etc., in fruits and vegetables produced around the world, as their use in the agricultural industry is not globally standardized. This reality has made GC–MS a valuable tool in the area of food safety and quality assurance.

Foods and beverages contain many aromatic compounds such as esters, fatty acids, alcohols, aldehydes, terpenes, etc., which may be naturally present or formed during processing, and the presence or absence of specific compounds may be of interest to researchers, food product developers, food inspectors etc. As stated above, GC–MS is mainly used to detect the presence or absence of pesticides in foods, but it can easily be expanded to detect contaminants arising from the spoilage or adulteration of food. GC–MS detected the presence of pesticides in pet food from China in 2007 (FDA 2007) as well as the presence of melanine in Chinese baby food in 2008. Both Kjeldahl and Dumas would have shown the presence of much higher than expected nitrogen content, and hence protein content, in the contaminated pet food and melamine adulterated baby food. The higher than expected protein content would have raised the suspicions of analysts, but further expensive and time-consuming tests would need to have been completed. In this case, GC–MS clearly demonstrated the presence of pesticides in the pet food and was also able to differentiate between the nitrogenous milk proteins and the nitrogen from the melanine.

In the world of expensive foods, GC–MS is an effective tool in the detection of food adulteration. Some food delicacies such as caviar, bird's nests, saffron, and truffles as well as other expensive food commodities such as coffee, tea, olive oil, balsamic vinegar, honey, maple syrup, etc., are commonly adulterated to levels that may not be detectable by conventional tests, and visual inspection may not raise the suspicions of food inspectors or consumers. Ruiz-Matate et al. (2007) reported the development of a GC–MS method to detect the adulteration of honey with commercial syrups. Honey can be adulterated with inexpensive sugar syrups such as high-fructose corn syrup or inverted syrups. Using GC–MS, they discovered, and were also the first to report, the presence of di-fructose in the four syrup samples but not in any of the honey samples. Hence, the presence of di-fructose in any honey sample would indicate possible adulteration of the honey. Likewise, Plessi et al. (2006) used GC–MS to discover the presence of nine phenolic antioxidant compounds in balsamic vinegar, an internationally and nationally recognized commodity that has country of origin status in the European Union (European Council Regulation 813/2000). These phenolic acids certainly contribute to the unique sensory qualities of the balsamic vinegar from Modena and may very well be used as specific identification markers indicating country, and region, of origin.

As adulteration can be fatally dangerous as well as compromise the integrity of the genuine food product, constant vigilance by advanced analytical methods such as GC–MS is critically necessary.

Enzymes in Food Analysis

Isaac N. A. Ashie

Abstract: Foods are primarily very complex matrices and therefore present an enormous technical challenge to the analyst whose responsibility is to determine and establish the levels of various components therein. A number of analytical tools, including enzymes, have therefore been developed through the years to meet this challenge. The basis for enzyme use is its specificity that enables selective, sensitive, and accurate determination of both macro- and micronutrients in foods. The application of enzymes as an analytical tool has, in recent years, been given a further boost by the development of biosensors with improved robustness and versatility. In this chapter, the application of enzymes (e.g., proteases, amylases, lipases, oxidases, etc.) and the underlying principles for analysis of food macro- and micronutrients including proteins, carbohydrates, lipids, antioxidants, cholesterol, toxins, food contaminants (pharmaceuticals, and food quality) are discussed.

INTRODUCTION

For centuries and prior to enzyme discovery and scientific understanding of its catalytic activity, humans had been inadvertently tapping into the benefits of enzymes for the production of a variety of foods. It is hard to think of food products like cheese, bread, wine, and other alcoholic beverages today without considering the role of enzymes in their production. Since their discovery, the unique characteristics of enzymes, such as their natural origins and specificity, have been exploited in the processing of a plethora of foods. These processes include (1) starch liquefaction and saccharification using alpha amylases and amyloglucosidases, (2) conversion of dextrins to fermentable sugars in brewing, (3) chill-haze prevention in the brewing industry using proteases, (4) juice clarification using pectinases, and (5) production of high-fructose corn syrups by conversion of glucose to its much sweeter keto-form, fructose, using glucose isomerase, just to mention a few. Recent developments in the field of molecular biology and protein engineering have enabled cost-effective production of "customized" enzymes with tailored characteristics that have further broadened the range of food applications involving enzymes. For example, phospholipases for increasing cheese yield and oil degumming, lipases for interesterification of lipids as an alternative to chemical processes, carbohydrate oxidases for lactose conversion to lactobionic acid used in the transplant industry for organ preservation, and asparaginases for acrylamide mitigation in foods are some of the emerging applications of enzymes in the food manufacturing process.

The broad range of enzyme classes used in the manufacture of food products is a very good indicator of the challenges presented to the food analyst, whose responsibility is to analyze the ingredients or components of different foods. Foods are basically a complex matrix of edible ingredients, some of which are present in high amounts (e.g., macronutrients such as

---

proteins, carbohydrates, and lipids) and others in extremely low amounts (e.g., flavor components, micronutrients such as vitamins, antioxidants, etc.). Analysis of these different components requires techniques that are not only simple and affordable but also, more importantly, very specific and sensitive to ensure that the "needle in the haystack" can be picked up (identified) and its size (amount) determined. These challenges have been largely met by technological advancements in chromatography, electrophoresis, mass spectrometry, etc. The specificity and relative sensitivity of enzymes make them ideally suited and versatile candidates for addressing these challenges as well. The protein nature of enzymes, however, means their efficacy for such applications is influenced by factors such as pH, temperature, and ionic strength of the analytes and the catalytic milieu. These factors tend to limit the scope of enzyme applications for this purpose as they may destabilize or denature the enzyme, compromise specificity, or reduce affinity of the enzyme for the substrate or analyte of interest. Some of these limitations have been addressed using immobilization techniques. Furthermore, the significant developments in biosensor technology provide an even greater opportunity for use of enzymes for this purpose by providing the necessary robustness, versatility, and affordability. Basically, biosensors are analytical tools consisting of two main components: (i) a bioreceptor for selective analyte or food ingredient detection and (ii) a transducer that transmits the resulting effect of the bioreceptor–analyte interaction to a measurable signal (Viswanathan et al. 2009). These signals may be amperometric, piezoelectric, potentiometric, fluorometric, or colorimetric. Furthermore, developments in biotechnology have made possible the commercial production, and thus availability, of a broad range of enzymes with the desired characteristics for use in such applications. This chapter is aimed at discussing the application of enzymes in analysis of foods, with emphasis on the principles underlying their role in these analyses. Obviously, any attempt at reviewing the analytical role of enzymes for all food components will be a massive endeavor that cannot be captured in one chapter, and there have been a number of reviews on the subject in the past, several of which have been appropriately cited. Therefore, the emphasis of this chapter is on the enzymatic methods for analysis of a few selected topics related to food components, including the major food components (i.e., proteins, carbohydrates, and lipids), toxins, contaminants, and food quality.

ANALYSIS OF THE MAJOR FOOD COMPONENTS

PROTEINS AND AMINO ACIDS

Proteins are major components of foods, and while the primary interest in proteins is due to their nutritional and functional impact on foods, the allergic reactions induced in sensitized individuals following consumption of certain proteinaceous foods have been a key driver for the development of highly selective and sensitive tools for protein detection and analysis to ensure that food products conform to regulatory standards. For example, lysozyme (muramidase) is an enzyme derived from hen egg white and is approved for use as an antimicrobial agent for preservation of the quality of ripened cheese. However, it is a potential allergen and the joint Food and Agricultural Organization/World Health Organization Codex Alimentarius Commission require its presence in foods to be declared on the label as an egg product (Codex Standard I-1985). Enzyme-linked immunosorbent assay (ELISA) has been a major technique for analysis of these and other proteins with limits of detection ranging from 0.05 to 10 mg/kg (Schubert-Ulrich et al. 2009). The widespread application of ELISA for these analyses has been attributed to its specificity, sensitivity, simple sample handling, and high potential for standardization and automation. Schneider et al. (2010) recently reported an ELISA for analysis of lysozyme in different kinds of cheese. Their method involved use of a peroxidase-labeled antibody that undergoes a redox reaction with tetramethylbenzidine dihydrochloride to form a product that can be measured by the absorbance change at 450 nm. A number of ELISA methods have been used for analysis of lysozyme in hen egg white, wines, cheese, and other foods (Rauch et al. 1990, Yoshida et al. 1991, Rauch et al. 1995, Vidal et al. 2005, Kerkaert and De Meulenaer 2007, Weber et al. 2007). Other proteins that have been analyzed by ELISA include those found in hazelnuts (Holzhauser and Vieths 1999), peanuts (Pomes et al. 2003), walnuts (Doi et al. 2008), soy (You et al. 2008), sesame (Husain et al. 2010), etc. In soybeans, as many as 16 allergenic proteins have been detected, of which β-conglycinin is considered to be the major culprit (Maruyama et al. 2001, Xiang et al. 2002). In the method of You et al. (2008) for β-conglycinin analysis, they had used an epitope corresponding to amino acid residues 78–84 of the protein to synthesize an immunogen by linking it (the epitope) to chicken ovalbumin and bovine serum albumin as carrier proteins. Horseradish peroxidase was used as the enzyme for detection by measuring absorbance at 492 nm. Table 3.1 shows a list of ELISA-based methods commercially available for analysis of a number of food proteins.

ELISA is a major enzyme-based analytical tool for a broad range of food components and other ingredients, and therefore, an explanation of the underlying principles is appropriate here. Figures 3.1 and 3.2 illustrate the general principles underlying the use of sandwich and competitive ELISA (both of which may be direct or indirect) for protein analysis. In the direct sandwich ELISA, a capture antibody specific for the protein being analyzed is first immobilized onto a solid phase. When analytes containing the protein of interest are introduced or present in the system or food material, they bind specifically to the immobilized antibody. Detection of such binding is achieved by introducing a second enzyme-labeled analyte-specific antibody into the system, thereby forming a sandwich. In the indirect sandwich ELISA, a second analyte-specific antibody binds to a secondary site on the protein of interest (analyte) to form the sandwich before the enzyme-labeled antibody binding. The requirement for a secondary binding site or more than one epitope for specific binding makes this type of ELISA primarily applicable to large molecules like proteins. In both types, the binding reaction may be linked to a chromophore, with the color intensity being proportional to the protein concentration.

Potentiometric, amperometric, electrochemical, and piezoelectric detection methods have since been developed and widely used for these analyses.

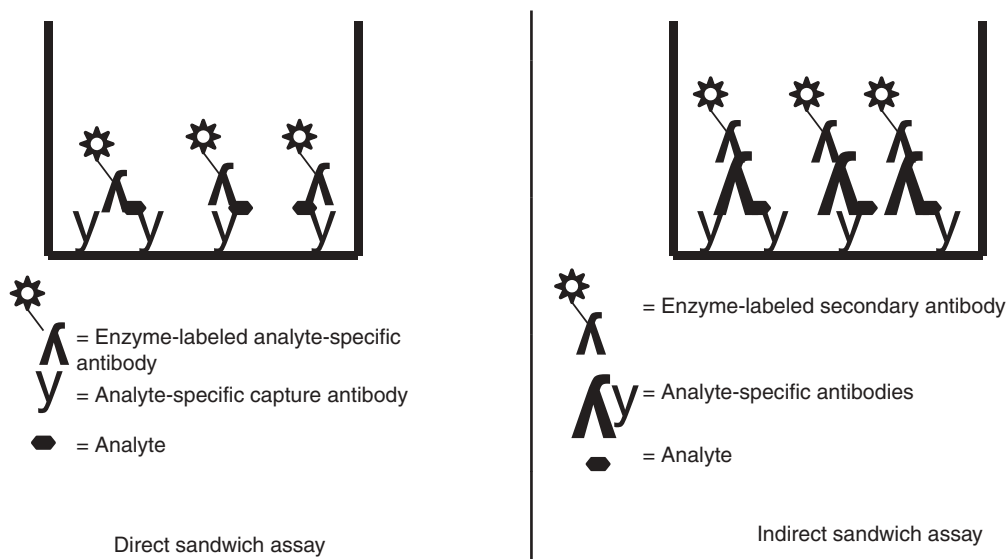
Competitive ELISA is more flexible and applicable to analysis of small as well as large molecules. In the direct form of the assay, the analyte of interest is first incubated together with the enzyme-labeled antibody and the mixture added to the analyte-specific capture antibody with which they react competitively and in a concentration-dependent manner for detection (Figure 3.2). The indirect form of competitive ELISA involves co-incubation of the bound analyte of interest with an analyte-specific antibody. Analyte detection is then achieved by introducing a second enzyme-labeled antibody into the mix, which binds to the analyte-specific antibody. In another form of indirect competitive ELISA, the analyte-specific antibody is first bound to the surface, and the analyte or protein of interest is made to compete with an enzyme-labeled analyte or a tracer for binding to the antibody. In all cases, the binding is concentration dependent and can be measured by the changes in absorbance or some other signal.


Figure 3.1. Sandwich ELISA with direct and indirect enzyme-labeled antibody detection.

Other techniques have been developed in recent years for protein or allergen analysis, which utilize enzyme-labeled antibodies for detection. These include lateral flow assays, which are immunochromatographic tests involving movement of immunoreactants along a test strip, and dipstick tests, which involve immobilized capture antibodies on a test strip with analyte detection by enzyme-labeled antibodies. Both techniques are generally inexpensive, rapid, and portable, thus making them ideal tools for online monitoring. For a detailed review of these techniques and other methods for protein and allergen analysis, the reader is referred to a recent review by Schubert-Ulrich et al. (2009). The growing field of nanotechnology has opened up other opportunities for development of enzyme-based biosensors for protein analysis. A recent report captured the essence of

Figure 3.2. Competitive ELISA with direct and indirect enzyme-labeled antibody detection.

this using gold-nanoparticle–carbon-nanotube hybrid linked to horseradish peroxidase as a biosensor for measuring the amount of protein in serum (Cui et al. 2008). In this method, the hybrid-bound peroxidase catalyzes oxidation of o-phenylenediamine in the presence of hydrogen peroxide to produce diaminobenzene, which, being electroactive, generates an amperometric response. Comparison of this method with ELISA showed no significant differences between the two methods. Table 3.1 shows a list of some commercially available ELISA kits for analysis of food proteins.

The free amino acid content as well as amino acid composition of food proteins constitutes very important food components due to their impact on general protein metabolism and a number of food qualities. For example, the presence of glutamate is generally associated with umami or savory flavor, while high content of hydrophobic amino acids tend to cause bitterness in protein hydrolysates. Similarly, high content of free amino acids provide free amino groups that promote Maillard reactions particularly when these foods are subjected to high-temperature treatments. The products or intermediates of the Maillard reaction may undergo other reactions that eventually influence flavor and color of the food product. In the age of protein-fortified sports drinks, free amino acid and peptide content of foods also provides the athlete the "boost" needed for recovery from intense muscle activity during fitness training. A number of analytical methods for determination of amino acid content in foods involve application of enzymes. For instance, one of the early methods for amino acid analysis involved the use of amino acid decarboxylases to decarboxylate amino acids. The stoichiometric release of carbon dioxide was then analyzed using glass electrodes containing sodium bicarbonate (Wiseman 1981). In the analysis of tryptophan, tryptophanase was used to catalyze hydrolysis of the amino acid to produce pyruvate. Coupling of the pyruvate production to lactate dehydrogenase converted NADH to NAD^+ and the corresponding change in absorbance at 340 nm was recorded as the index of tryptophan content (Wiseman 1981). The principle underlying the method is shown in Figure 3.3. A similar method involving coupling to NADH has been exploited in the aspartate aminotransferase analysis of aspartic acid by conversion of aspartic acid to oxaloacetate in the presence of malate dehydrogenase (Wiseman 1981). A number of

Figure 3.3. Principle underlying tryptophan analysis in foods using the coupled tryptophanase and lactate dehydrogenase (LDH) reaction.

other enzyme-based methods have been developed for analysis of amino acids, with a significant number of these also using coupling to NADH–NAD^+ conversion (see Table 3.2).

SUGARS

Glucose oxidase is by far the most predominant and widely used of enzymes for detection of glucose in foods. The underlying principle is based on hydrolysis of glucose to form gluconic acid and hydrogen peroxide. The latter is then coupled to peroxidase catalysis, which oxidizes a colored precursor, resulting in absorbance change that is proportional to the glucose content (Wiseman 1981). Other methods using enzyme complexes or combinations for analysis of glucose are available. One such method was based on the glucose-6-phosphate transferase catalyzed transfer of an acyl phosphate from a donor molecule to form glucose 6-phosphate. Coupling this reaction to NADP conversion to NADPH resulted in absorbance change that could be measured at 340 nm. Glucose oxidase has also been applied to the determination of sucrose (common sugar). The analysis involves invertase-catalyzed conversion of sucrose to D-fructose and α-D-glucose. This is followed by mutarotase-catalyzed isomerization of the α-D-glucose to β-D-glucose, which in turn is oxidized by glucose oxidase to D-glucono-δ-lactone and hydrogen peroxide (Morkyavichene et al. 1984, Matsumoto et al. 1988). As discussed earlier, the amount of peroxide released by the coupled reaction with peroxidase is proportional to the sucrose content. Fructose is another monosaccharide with widespread use in several foods and thus of significant interest in the food industry. The level of fructose in foods provides an indication of the stage of ripening, adulteration of products such as honey, and the sweetness of various foods. There have been several analytical methods based on the highly specific pyrroloquinoline quinone (PQQ) enzyme, D-fructose dehydrogenase (Paredes et al. 1997). The enzyme catalyzes oxidation of D-fructose to 5-keto-D-fructose with corresponding reduction of the covalently bound cofactor PQQ to $PQQH_2$. Coupling reoxidation of the reduced cofactor to electrodes produces electric current in direct proportion to the amount of fructose. Trivedi et al. (2009) recently reported another method involving use of D-fructose dehydrogenase with ferricyanide as electron acceptor. Figure 3.4 is a schematic representation of the principle underlying this method. The enzyme oxidizes fructose to keto-fructose with the reduction of ferricyanide. The reduced ferricyanide is subsequently re-oxidized, producing electrical current proportional to fructose concentration.

In a recent review, Zeravik et al. (2009) discussed the use of biosensors referred to as bioelectronic tongues for detection and analysis of sugars and other food components or contaminants. Glucose and ascorbic acid content of fruit juices have been analyzed using one of these "tongues" involving glucose oxidase and metal catalysts (Pt, Pd, and Au–Pd). The metal catalysts improved the sensitivity of the tongue by reducing the oxidation potential of the hydrogen peroxide released as a result of the glucose oxidase activity (Gutes et al. 2006). Similar simultaneous detection of glucose, fructose, and sucrose has been achieved by amperometric flow injection analysis using an immobilized

enzyme reactor (Matsumoto et al. 1988). In the analysis of wine components, Zeravik et al. (2009) have discussed the use of (a) PQQ-bound dehydrogenases for the determination of glucose, alcohol, and glycerol; (b) tyrosinase, laccase, and peroxidase for phenolic compounds; and (c) sulfite oxidase for sulfite content.

For analysis of starch, a complex polysaccharide, the underlying principles of starch liquefaction and saccharification are utilized. The α-amylases hydrolyze starch, releasing maltose units and limit dextrin. This is characterized by viscosity reduction or what is more commonly referred to by the starch industry as liquefaction. Further treatment with pullulanase and amyloglucosidases (glucoamylases) results in hydrolysis of the maltose units and limit dextrin, ultimately producing glucose units that are subsequently analyzed by some of the methods discussed earlier. Figure 3.5 illustrates the salient features of the amylase, pullulanase, and amyloglucosidase reaction. Analyses of other polysaccharides have been conducted in similar fashion by initial breakdown to simpler sugars using different carbohydrases depending on the nature of the substrate. Dextranases have been used for dextrans, cellulases for cellulose, hemicellulases for hemicelluloses in dietary fiber, and pectinases and polygalacturonases for polysaccharides in soy sauce and other plant-based foods (Wiseman 1981). Table 3.2 provides a list of

some of the enzymatic methods for food component analysis along with some of the commercially available test kits.

OTHER FOOD COMPONENTS

Alcohol

Alcohol (ethanol) content in beer, wine, and other alcoholic beverages is a very important quality attribute and is also required for regulatory classification. The NAD-dependent alcohol dehydrogenase is widely used for analysis of alcohol content in foods and alcoholic beverages. The enzyme catalyzes oxidation of ethanol to acetaldehyde in an equilibrium reaction that also produces NADH. The reaction is made to proceed in the forward direction by acetaldehyde reaction with semicarbazine or hydrazine. The absorbance change resulting from NAD^+ to NADH conversion is proportional to alcohol content. Similar NAD-dependent assays have been used for measuring glycerol content in foods. Figure 3.6 shows the principle underlying the method for glycerol analysis.

Cholesterol

Consumption of cholesterol-rich foods and their association with atherosclerosis, hypertension, and high incidence of other

(**A**) With amylose as substrate, amylase hydrolyzes the starch to maltose units, which are further simplified to glucose units. (**B**) With amylopectin substrate, pullulanase hydrolyzes the limit dextrin resulting from amylase activity. The products are further simplified by the amylase and glucoamylase to release glucose units.

cardiovascular disease has generated strong interest in the level of cholesterol in foods. Some foods characterized by high levels of cholesterol are cheese, egg yolk, beef, poultry, shrimps, and pork. The earliest enzymatic methods for cholesterol analysis were based on colorimetric assays involving initial de-esterification of cholesterol esters by cholesterol esterase to release free cholesterol, which is further oxidized by cholesterol oxidase to generate hydrogen peroxide. The peroxide produced is subsequently coupled to a colored or fluorescent reagent in a peroxidase-catalyzed reaction (Satoh et al. 1977, Hamada et al. 1980, Omodeo et al. 1984, Van Veldhoven et al. 2002). A commercial kit (Boehringer's Monotest cholesterol or CHOD-PAP method) for the colorimetric assay is available, in which 4-aminoantipyrine and phenol are converted to a red cyanogenimine dye in the presence of the peroxide released. New and more sensitive electrochemical biosensors have since been developed involving immobilization of the enzymes (cholesterol esterase and cholesterol oxidase) on electrode surfaces and carbon nanotubes (Wisitsoraat et al. 2009). Similarly, a number of other enzyme-immobilized biosensors originally developed for analysis of serum cholesterol may also be applicable to food analysis. These include immobilization on polyvinyl chloride with glutaraldehyde as a coupling agent (Hooda et al. 2009), agarose gel and activation with cyanogen bromide (Karube et al. 1982), and pyrrole membrane coupled with flow injection for hydrogen peroxide analysis (Wolfgang et al. 1993).

Antioxidants

Oxidation of lipids in foods has been an age-old problem of the food industry due to the free-radical-induced off-flavors and the implication of these free radicals in cell damage and a number of pathogenetic conditions. Controlling such oxidation has been largely achieved by a number of process modifications as well

Figure 3.6. Glycerolkinase and glycerol dehydrogenase for glycerol analysis in foods.

as incorporation of antioxidants in various food product for-
mulations. Though generally added for their ability to maintain
food quality during processing and storage, antioxidants are also
considered to protect consumers against some of the potential
health risks associated with free radicals. An enzymatic assay
recently developed for antioxidant analysis involves oxidation
of the yellowish compound syringaldazine by laccase to pro-
duce the purple-colored tetramethoxy azobismethylene quinone
(TMAMQ) with maximum absorbance at 530 nm. In the pres-
ence of antioxidants, the free-radical intermediates are unavail-
able or converted, thereby proportionately blocking formation
of the purplish TMAMQ (Prasetyo et al. 2010). This method
has been used to measure the level of antioxidant activity in a
wide range of fruits and vegetables (e.g., apples, carrots, gar-
lic, kiwi, lettuce, spinach, tomatoes), beverages (e.g., green tea,
coffee), and oils. While in most cases, enzymes have been used
for specific identification and analysis of these ingredients, they
have also been used in extraction of some compounds for anal-
ysis. Analysis of flavanoids, which are often present in foods
as the glycosylated or sulfated derivatives, generally involves
enzymatic hydrolysis to the corresponding aglycones and desul-
fated forms during their extraction. Typically used in the extrac-
tion process are the β-glucuronidase or β-glycosidases and aryl
sulfatase, as demonstrated in a recent report for determination
of hesperitin and naringenin in foods (Shinkaruk et al. 2010).
The extracted products were then subjected to peroxidase-linked
ELISA.

Organic Acids

The presence and content of organic acids has long been known
to exert significant influence on quality attributes of a wide
variety of food products, including wines, milk, vinegar, soy
sauce, and fermented products. Therefore, a number of enzy-
matic methods have been developed to detect and quantify these
acids such as lactic, acetic, citric, malic, ascorbic, and succinic
acids in a number of food products (Wiseman 1981). Also see
Table 3.2.

The most widely studied of these acids is lactic acid due to
its impact on a broad range of food products. In yogurt pro-
duction and cheese maturation, lactic acid is a major interme-
diate of *Lactobacillus* fermentation and determines the flavor
of the final product. In wine production, organic acids impact
flavor, protect against bacterial diseases, and may slow down
ripening. Excessive lactic acid in wines has a negative effect
on wine taste due to formation of acetate, diacetyl, and other
intermediates. These irreversible transformations designated by
the French term "piqure lactique" have been attributed to the ac-
tivities of some heterolactic bacteria during malo-lactic fermen-
tation, which compromises wine race (Avramescu et al. 2001,
Shkotova et al. 2008). Lima et al. (1998) developed a method
for the simultaneous measurement of both lactate and malate
levels in wines. This involved injection of enzymes (malate de-
hydrogenase and lactate dehydrogenase) into a buffer carrier
stream flowing to a dialysis unit, where they react with the wine
donor containing the two acids. Detection is based on absorbance
change at 340 nm due to reduction of NAD^+ to NADH. Simi-

lar NAD^+-dependent lactate dehydrogenase application for lac-
tate analysis has been developed using amperometric biosensors
(Avramescu et al. 2001, 2002). Another enzymatic method for
lactate determination in wines is the immobilized FAD-bound
lactate oxidase. The enzyme catalyzes conversion of lactate to
pyruvate and peroxide. Decomposition of the hydrogen perox-
ide results in generation of electrons that are recorded by an
amperometric transducer. Table 3.2 lists a number of enzymatic
methods and commercial test kits used for analysis of various
acids in foods.

ANALYSIS OF FOOD CONTAMINANTS

PHARMACEUTICALS

The growing use of antibiotics and other drugs for treatment of
animals meant for food (e.g., cattle, chicken, pigs) is of great
concern to regulatory authorities due to the potential carry-over
effect on consumers as these drugs enter the food supply. This
has led to strict regulations on the prophylactic and therapeutic
use of these drugs being introduced in many countries. There-
fore, a number of methods have been developed for analysis
of these drugs to ensure food safety. For instance, the high inci-
dence of aplastic anemia in some countries has been attributed to
the use of chloramphenicol in the treatment of food-producing
animals, particularly aquaculture (Bogusz et al. 2004). Clen-
buterol, a β-adrenergic agonist widely used in the treatment of
some pulmonary diseases, also promotes muscle growth, and
therefore, it is sometimes abused in animal feed to boost the
lean meat-to-fat ratio and as a doping agent by athletes (Clarkson
and Thompson 1997). Prolonged use of clenbuterol is known to
cause adverse physiological effects, and incidents of poisoning
have been reported in many countries following consumption of
foods containing high concentrations of the drug (Pulce et al.
1991). ELISA methods based on monoclonal and polyclonal
antibodies are the most widely used of the enzymatic methods
for analysis (Petruzzelli et al. 1996, Matsumoto et al. 2000).
He et al. (2009) recently reported development of a polyclonal
indirect ELISA with high sensitivity for clenbuterol analysis in
milk, animal feed, and liver samples. Another set of drugs sub-
ject to European Union Maximum Residual Limits are the nons-
teroidal anti-inflammatory drugs (NSAIDs) used for treatment of
some food-producing animals (porcine and bovine). Consump-
tion of meat products containing these drugs has been shown
to cause gastrointestinal problems such as diarrhea, nausea, and
vomiting by irritation of the gastric mucosa. A simple enzy-
matic method involving cyclooxygenase has been developed
for analysis of NSAIDs in milk and cheese (Campanella et al.
2009). In absence of NSAIDs, cyclooxygenase catalyzes oxida-
tive conversion of arachidonic acid to prostaglandins. However,
the presence of NSAIDs results in competitive inhibition of this
activity, thereby reducing prostaglandin synthesis. The NSAID
concentration is detected by coupling the catalytic reaction with
an amperometric electrode for oxygen. Chloramphenicol, a po-
tent broad-spectrum antibiotic banned in Europe and the United
States due to potential toxic effects (aplastic anemia), is gen-
erally analyzed using various conventional methods such as

gas chromatography, immunoassay, and mass spectrometry. The drug tends to be conjugated in biological systems, and Bogusz et al. (2004) recently developed an assay to distinguish between the free and conjugated forms. They used β-glucuronidase in the extraction process to hydrolyze the conjugated to the free form, enabling selective analysis of the drug in honey, shrimps, and chicken.

Fluoroquinolones, antimicrobial agents used for treatment and disease prevention in food-producing animals and sometimes used as feed additives to build up animal body mass, is another group of drugs that has come under scrutiny. This is due to their misuse, potentially leaving residues in meats, which could lead to drug resistance and allergic hypersensitivity (Martinez et al. 2006). Therefore, maximum residue limits have been instituted in the European Union, and a number of ELISA methods have been developed for their detection in milk, chicken, pork, eggs, and other foods (Coillie et al. 2004, Huet et al. 2006, Lu et al. 2006, Scortichini et al. 2009, Sheng et al. 2009). Euro Diagnostica B.V. (Arnhem, Netherlands) has a commercial kit currently available for analysis of quinolones.

Melamine is a triazine compound that contains 67% nitrogen and is used in the production of plastics, construction materials, and furniture. This compound was brought to public attention in the fall of 2008 following growing incidents of infants coming down with kidney stones in China as a result of adulteration of infant formula with the compound. Similar melamine adulteration in an effort to raise the apparent protein content of pet foods resulted in several pet deaths. These incidents were presumably possible due to protein analysis of foods being routinely conducted with the Kjeldahl method, which is nonspecific and does not distinguish between protein and nonprotein nitrogen. Several alternative methods for detection of melamine and related compounds (cyromazine, ammelide, cyanuric acid, and ammeline), including ELISA, have been developed and implemented (Tittlemier 2010) to ensure food safety. Romer Labs and Beacon Analytical Systems have commercially available ELISA test kits for melamine analysis in a broad range of foods.

Biotechnology, and particularly genetic modification, is undoubtedly a key factor for addressing the challenge of boosting food supplies to meet the demands of an exploding global population. This is clearly evident by the increase in the global area cultivated for biotech crops from 1.7 million hectares in 1996 to 125 million hectares in 2008 with the major food crops being soybean, canola, and maize (Lee et al. 2009). However, there is a deep sense of cynicism over the potential health and environmental impact of GMO-based foods. There have been calls for controls on GMO, and strict regulations on traceability and labeling of GMO and foods or feed made from GMO technology have been established in many countries (Council Regulation 2000, Lee et al. 2009). Hence, a number of detection and quantification methods have been developed based on analysis of two main components characteristic to GMO: (i) a specific transgenic DNA and (ii) a specific novel protein expressed by the GMO. The basic principle underlying these methods is the use of the polymerase chain reaction (PCR) to establish the presence of the most common recombinant elements in the vast majority of genetically modified crops (Vollenhofer et al. 1999, Miche-

lini et al. 2008, Lee et al. 2009). These are the 35S promoter and nopalin synthetase (NOS) terminator, both of which are transcription sequences (Barbau-Piednoir et al. 2010). Variations of this method have been used to detect and quantify GMO in soy, maize, and other food crops (Matsuoka et al. 2001, James et al. 2003, Meric et al. 2004, Yang et al. 2006, 2007, Wu et al. 2007, Lee et al. 2009, Costa et al. 2010). In one of these methods, a disposable genosensor for detecting the NOS terminator (Meric et al. 2004) was used. It involved immobilization of a synthetic single stranded 25-base oligonucleotide that is complimentary to the NOS terminator to a screen-printed carbon electrode. In the presence of exogenous genetic materials, DNA polymerase catalyzes the PCR to synthesize the complimentary base sequence. Detection of hybridization is achieved by monitoring the reduction signal from the high-affinity binding of methylene blue to guanine.

In the alternative method based on detection of expressed proteins by the genetically modified organisms, PCR-ELISA has been the preferred approach and has been used for detecting and quantifying various GMO materials. This is demonstrated by the use of a sandwich ELISA for the detection of the Cry1Ab endotoxin characteristic of some transgenic maize. A Cry1Ab protein-specific antibody was first immobilized on a microtiter plate to capture the Cry1Ab toxin in the sample. This was followed by a second anti-Cry1Ab antibody and a horseradish peroxidase-labeled antibody for detection of the toxin using a chemiluminescent probe (Roda et al. 2006). A similar sandwich ELISA has been developed for the detection of phosphinotricin-N-acetyltransferase, which is encoded by a gene in genetically modified pepper (Shim et al. 2007). Using two commercially available ELISA kits, Whitaker et al. (2001) detected and quantified the distribution and variability of the Cry9C insecticidal protein produced by the genetically modified corn (StarLink) in a bulk of corn flour and meal. There are a number of other reports of PCR-ELISA application for GMO analysis in soy and maize products (Landgraf et al. 1991, Brunnert et al. 2001, Petit et al. 2003).

FOOD TOXINS

Food toxicity is of high importance due to their potential impact on safety and risk to the environment. These toxins may be naturally present (endogenously), process induced, or from the environment. Food toxins such as phytotoxins (terpenoids, glycoalkaloids, phytosterols, flavonoids, lignans) and mycotoxins (aflatoxins, fumonisins, ochratoxins, citrinin, mycophenolic acid, etc.) are all naturally occurring and their toxic effects have been well noted. This section discusses the enzymatic methods for analyses of these and other toxins.

Endogenous Toxins

Mycotoxins are toxic secondary metabolites produced by various fungi (*Aspergillus, Fusarium, Penicillium,* etc.) and excreted in their substrates. Aflatoxins first came to the attention of researchers following the outbreak of the so-called Turkey X disease among turkeys in the 1960s and is by far the most widely

studied of the mycotoxins. It has since been shown to occur mainly in the tropics in such food ingredients as peanuts, pistachios, Brazil nuts, walnuts, cottonseed, maize, and other cereal grains such as rice and wheat. Aflatoxins are considered to induce hepatotoxicity, mutagenicity, teratogenicity, immunosuppressant, and carcinogenic effects, and their presence in foods is highly regulated at a level of 0.05–2 μg/kg in the European Union (EC Report 2006). With such low limits, the analytical methods need to be of high sensitivity and specificity, and ELISA has developed to be one of the main methods for aflatoxin analysis. Some of the enzymes that have been used include horseradish peroxidase, which oxidizes tetramethylbenzidene to a product that can be measured by its electrical properties, and alkaline phosphatase for dephosphorylation of naphthyl phosphate to naphthol that is measured by pulse voltametry (Ammida et al. 2004, Parker and Tothill 2009). Detection limits for these methods were in the range of 20–30 pg/mL. Other ELISA methods for aflatoxin analysis have been reported (Lee et al. 2004, Liu et al. 2006, Jin et al. 2009, Piermarini et al. 2009, Tan et al. 2009). In their method, Liu et al. (2006) developed a biosensor by immobilizing horseradish peroxidase and aflatoxin antibodies onto microelectrodes. The presence of aflatoxin in the food resulted in immunocomplex formation with the antibody, which blocked electron transfer between the enzyme and the electrode, thereby modifying conductivity in proportion to aflatoxin concentration. Similar ELISA methods involving alkaline phosphatase and horseradish peroxidase has been used for analysis of ochratoxin A in wine (Prieto-Simon and Campas 2009). A fast and sensitive spectrophotometric method has also been reported based on acetylcholinesterase inhibition by aflatoxin (Arduini et al. 2007).

Unlike aflatoxins, which are mainly associated with foods from warm tropical regions, trichothecene mycotoxins are commonly found in cereals like wheat, barley, maize, oats, and rye, particularly in cold climates. Like the aflatoxins, these have also been found to cause immunosuppressive and cytotoxic effects as well as other disorders due to their inhibition of protein, DNA, and RNA synthesis. AOAC-approved methods (www.aoac.org/testkits/testedmethods.html) based on ELISA kits are commercially available for analysis of trichothecenes. These include the RIDASCREEN FAST and AgraQuant manufactured by Biopharm GmbH and Romer Labs, respectively, using horseradish peroxidase (Lattanzio et al. 2009).

Linamarin and lotaustralin are cyanogenic glycosides considered toxic and found in food crops like lima beans and cassava. The endogenous linamarase released on tissue damage hydrolyzes the glucosides to produce hydrogen cyanide, a highly toxic compound (Cooke 1978). In the analysis of these toxins, the endogenous linamarase is first inactivated, followed by introduction of the exogenous enzyme. The cyanide produced as a result of the enzyme activity is then measured by a spectrophotometer as index of toxin content. The linamarase-catalyzed reaction normally exists in equilibrium but is made to proceed in the forward direction by alkali treatment (Cooke 1978).

Biogenic amines are organic bases found in a broad range of foods such as meat, fish, wine, beer, chocolate, nuts, fruits, dairy products, sauerkraut, and some fermented foods, but are potentially toxic when consumed. These amines, most of which are produced by microbial decarboxylation of the corresponding amino acids, include putrescine, cadaverine, tyramine, spermine, spermidine, and agmatine. That is, putrescine, histamine, tryptamine, tyramine, agmatine, and cadaverine are formed from ornithine, histidine, tryptophan, tyrosine, arginine, and lysine, respectively (Teti et al. 2002). Histamine is the most regulated of these amines. In Germany, the maximum limit in fish products is set at 200 mg/kg, whereas in Canada, Finland, and Switzerland, it is set at 100 mg/kg. Various methods have been developed for analysis of these compounds (Onal 2007). For histamine determination, one of the methods has been based on the sequential activities of diamine oxidase and horseradish peroxidase (Landete et al. 2004). The diamine oxidase catalyzes breakdown of histamine, releasing imidazole acetaldehyde, ammonia, and hydrogen peroxide. The hydrogen peroxide produced is oxidized by the peroxidase, resulting in color change of a chromogen, which is measured by a colorimeter. Muresan et al. (2008) recently developed an amperometric biosensor involving use of amine oxidase and horseradish peroxidase for amine detection. In this method, the amines were first separated on a weak acid cation exchange column followed by enzymatic reactions that produce a potential difference, which is measured by a bioelectrochemical detector. An enzyme sensor array for simultaneous detection of putrescine, cadaverine, and histamine has also been reported by Lange and Wittman (2002). The principle underlying the method is illustrated in Figure 3.7. Changes in the levels of the various biogenic amines during ageing of salted anchovies were determined using immobilized diamine oxidase coupled to electrochemical detection of the hydrogen peroxide produced by the enzyme activity (Draisci et al. 1998).

Process-Induced Toxins

Acrylamide is a process-induced toxin that has gained significant global attention in the past decade following a publication by the Swedish National Food Administration (2002), which indicated its widespread presence in numerous food products and the risk posed to humans from consumption of such foods. Foods considered to have high levels of acrylamide include baked and fried products like potato chips (or crisps), biscuits, crackers, breakfast cereals, and French fries. The mechanism of acrylamide formation in these foods is attributed to the high levels of asparagine in the raw materials (especially wheat and potatoes) used in their production. Initiation of the Maillard reaction in presence of reducing sugars with asparagine as amino group donor channels the complex series of reactions through a pathway that results in the production of acrylamide (Mottram et al. 2002). While methods involving gas chromatography, liquid chromatography, and mass spectrometry still dominate analysis of this compound, a recent report has demonstrated the potential application of ELISA for analyzing acrylamide content in foods (Preston et al. 2008). To overcome the problem with the small size of acrylamide, which has limited the use of immunoassay for its analysis, these authors derivatized acrylamide with 3-mercaptobenzoic acid (3-MBA) and conjugated that to a carrier protein (bovine thyroglobulin) to form an
Enzymatic reaction:

$$R\text{-}CH_2\text{-}NH_2 \quad + \quad O_2 \quad + \quad H_2O \xrightarrow{\text{Amine oxidase}} R\text{-}CHO \quad + \quad NH_3 \quad + \quad H_2O_2$$

Color reaction:

$$H_2O_2 \quad + \quad \text{Reduced dye (colorless)} \xrightarrow{\text{Peroxidase}} H_2O \quad + \quad \text{Oxidized dye (colored)}$$

Electrochemical reaction:

$$H_2O_2 \longrightarrow O_2 \quad + \quad 2H^+ \quad 2e^-$$

Figure 3.7. Principle underlying amine detection by coupling amine oxidase and peroxidase reactions.

immunogen. Antisera raised against the immunogen and shown to have high affinity for the 3-MBA-derivatized acrylamide was used in the development of a peroxidase-based ELISA detection system with about 66 μg/kg limit of detection. A commercial ELISA kit has been recently introduced by Abraxis (www.abraxis.com) for acrylamide analysis.

Environmental Toxins

Certain toxin-producing phytoplanktons present in the aquatic environment have generally been recognized as the source of marine toxins in the human food chain following consumption of contaminated fish and shellfish. Safety concerns have led to regulatory limits being set for the presence of these toxins in seafoods.

Okadaic acid and its derivatives, which are considered responsible for diarrheic shellfish poisoning, are very potent inhibitors of protein phosphatase, and a number of methods have been developed around inhibition of the enzyme for its analysis (Tubaro et al. 1996, Della Loggia et al. 1999, Campas and Marty 2007, Volpe et al. 2009). Analysis of this toxin has also been accomplished by ELISA methods (Kreuzer et al. 1999, Campas et al. 2008). The toxic effects of yessotoxins remain to be elucidated even though in vitro studies indicate cardiotoxicity. Analytical methods based on ELISA (Garthwaite et al. 2001, Briggs et al. 2004) and yessotoxin interaction with pectinesterase enzymes have been developed (Alfonso et al. 2004, Pazos et al. 2005, Fonfria et al. 2008).

Another group of marine toxins of relevance to food are the brevetoxins responsible for neurotoxic shellfish poisoning. The inhibition by brevetoxins of the desulfo-yessotoxin interaction with phosphodiesterase provided the basis for an analytical method (Mouri et al. 2009), and also reported are various ELISA methods (Baden et al. 1995, Garthwaite et al. 2001, Naar et al. 2002). Saxitoxins, responsible for paralytic shellfish poisoning, have been analyzed in foods by ELISA (Chu and Fan 1985, Garthwaite et al. 2001). The paralytic effect is attributed to their high-affinity binding to specific sites on sodium channels, thereby blocking sodium flux across excitable cells. Like the

saxitoxin group of toxins, amnesic shellfish poisoning is associated with consumption of foods contaminated with the domoic acid group of water-soluble neurotoxins produced by the genera *Pseudonitzschia*, *Nitzschia*, and *Chondria armata* (Vilarino et al. 2009). Ciguatoxin poisoning is characterized by symptoms of nausea, diarrhea, abdominal cramps, memory loss, dizziness, headaches, and death in extreme cases. An ELISA method approved by AOAC has been adopted in many countries (Kleivdahl et al. 2007). Tsai et al. (2009) have reported the identification of moray eel species responsible for ciguatera poisoning based on analysis of the cyt b gene in mitochondrial DNA using the PCR and restriction enzymes. In a recent study, Garet et al. (2010) compared relative sensitivities of ELISA and conventional methods (HPLC-UV and mouse bioassay) for detection of amnesic shellfish poisoning and paralytic shellfish poisoning toxins in naturally contaminated fresh, frozen, boiled, and canned fish and shellfish. Their findings showed lower limits of detection (50 μg saxitoxin and 60 μg per kg shellfish meat for saxitoxin and domoic acid, respectively) compared to 350 μg saxitoxin and 1.6 mg domoic acid per kg shellfish meat, respectively, when analyzed by conventional methods.

Detection of marine palytoxins and tetrodotoxins using ELISA techniques have also been reported (Bignami et al. 1992, Lau et al. 1995, Rivera et al. 1995, Kawatsu et al. 1997, Kreuzer et al. 2002, Neagu et al. 2006). Palytoxins and their analogues elicit their toxic effects by binding to the Na^+/K^+ ATPase pumps, thereby altering the selectivity of ion flux and membrane potential. Much like the saxitoxins, the tetrodotoxins elicit their neurotoxicity by inhibiting voltage-gated sodium channels. The method of Kreuzer et al. (2002) for analysis of tetrodotoxins involves an alkaline phosphatase-labeled antibody, the activity of which produces p-aminophenol, which can be detected by the amount of current generated. Alkaline phosphatase activity is competitively inhibited by tetrodotoxin, thereby reducing the current produced.

The presence of pesticides in foods and their impact on health is an issue of critical concern to the food industry, and therefore, regulatory measures are in place establishing maximum residual limits. Inhibition of acetylcholinesterase by pesticides has

formed the basis for a broad range of techniques for pesticide analysis (see reviews by Mulchandani et al. 2001, Amine et al. 2006). These have used:

1. amperometric transducers to measure thiocholine and p-aminophenol produced by acetylcholinesterase hydrolysis of butyrylthiocholine, and p-aminophenyl acetate or hydrogen peroxide produced by oxidation of choline following acetylcholine hydrolysis in presence of choline oxidase;
2. potentiometric transducers for measuring pH changes as a result of acetic acid production from enzyme activity;
3. fiber optics for monitoring pH changes using a fluorescein-labeled enzyme.

These acetylcholinesterase inhibitory methods, however, are nondiscriminating between the organophoshates, carbamates, and other pesticides. In their review, Mulchandani et al. (2001) have discussed the use of organophosphorus hydrolase integrated with electrochemical and optical transducers to specifically measure organophosphate pesticides. The enzyme hydrolyzes organophosphates to produce acids or alcohols, which generally tend to be either electroactive or chromophores that can be monitored.

Bioelectronic tongues have also been proposed for the detection of pesticides such as organophosphates, carbamates, as well as phenols using an amperometric bioelectronic tongue involving cholinesterase, tyrosinase, peroxidases, and cellobiose dehydrogenase. The corresponding substrates for the enzymes were acetylcholine, phenols, hydrogen peroxide, and cellobiose, respectively, with detection limits in the nanomolar and micromolar range (Solna et al. 2005). A similar bioelectronic tongue with acetylcholinesterase as biosensor has been used to resolve pesticide mixtures of dichlorvos and methylparaoxon (Valdez-Ramirez et al. 2009).

Botrytis, a fungal disease responsible for significant losses of agricultural produce particularly in vineyards (e.g., wine grapes, strawberries), is controlled by preharvest or postharvest treatment with the fungicide fenhexamid, which inhibits growth of the germ tube and mycelia of the fungus. Detection and analysis of fenhexamid levels in must and wines have been accomplished by direct competitive ELISA containing horseradish peroxidase (Mercader and Abad-Fuentes 2009). Atrazine, a herbicide with widespread contamination of waterways and drinking water supplies and implicated in certain human health defects (e.g., birth defects, menstrual problems, low birth weight), is tightly regulated in the European Union with a limit of 0.1 g/L in potable water and fruit juices. Conductimetric and amperometric biosensors based on tyrosinase inhibition have been developed for the analysis of atrazine and its metabolites (Hipolito-Moreno et al. 1998, Vedrine et al. 2003, Anh et al. 2004). The method is based on deactivation of tyrosinase under aqueous conditions. The enzyme normally catalyzes oxidation of monophenols to o-diphenols, which are eventually dehydrogenated to the corresponding o-quinones. In aqueous environments, these form polymers that inhibit the enzyme (Hipolito-Moreno et al. 1998). Therefore, atrazine inhibition of the enzyme is conducted in nonaqueous media, where the quinone effect is eliminated, thus ensuring the inhibition is primarily due to the herbicide. Some

recent reviews have also captured the application of enzymatic biosensors for determination of fertilizers (nitrates, nitrites, and phosphates), as well as several pesticides and heavy metals that are potentially toxic to humans when they enter the food chain (Amine et al. 2006, Cock et al. 2009). Some of the enzymes applied to these analyses include (i) urease, glucose oxidase, acetylcholinesterase, alkaline phosphatase, ascorbate oxidase, alcohol oxidase, glycerol-3-phosphate oxidase, invertase, and peroxidase for heavy metals and (ii) nitrate reductase, polyphenol oxidase, phosphorylase, glucose-6-phosphaste dehydrogenase, and phosphoglucomutase for nitrates, nitrites, and phosphates.

ENZYMATIC ANALYSIS OF FOOD QUALITY

While enzymes generally exert positive influence on food quality, the activities of some enzymes need to be controlled postharvest or postprocessing to avoid compromising the quality of food products. For instance, protease activity is desirable for meat tenderization during ageing, but left uncontrolled, meats become mushy and overtenderized. Similarly, excessive lipase and oxidase activities in foods during storage, especially under temperature-abuse conditions, may cause rancidity and impact quality attributes such as color, flavor, and texture. Therefore, a number of preservation techniques developed through the years have been aimed at controlling such undesirable postharvest enzymatic as well as microbial activities to ensure extended shelf life of food products.

The activities of a number of enzymes as well as the content of certain food components and secondary metabolites resulting from postharvest or postprocessing biochemical and microbial activities have been recognized as quality indices for various foods and consequently monitored. An example is the milk endogenous alkaline phosphatase, which is inactivated following heat treatment at 60°C for 5 seconds. With milk generally subjected to HTST/flash pasteurization (i.e., 71.5–74°C/160–165°F for 15–30 seconds) or ultra-high-temperature treatment (i.e., 135°C/275°F for 1–2 seconds), residual alkaline phosphatase activity following such treatment provides a good indication of efficacy of the treatment. The phosphatase test is based on hydrolysis of disodium phenyl phosphate to liberate phenol, which reacts with dichloroquinonechloroimide to form a blue indophenol that is measured colorimetrically at 650 nm (Murphy et al. 1992). An alternative fluorimetric method for alkaline phosphatase analysis has also been developed and commercialized (Rocco 1990). The adequacy of blanching, an essential step in vegetable processing, is also established by measuring residual lipoxygenase or peroxidase activities (Powers 1998). Amylase activity in malt, also referred to as its diastatic power, is a very essential quality parameter that influences dextrinizing time and, therefore, closely monitored (Powers 1998). In most seafoods, freshness is rapidly compromised postharvest, particularly when handled under temperature-abuse conditions that promote endogenous enzyme activity. The sequence of reactions (Figure 3.8) involved in ATP breakdown in postmortem fish

$$ATP \Rightarrow ADP \Rightarrow AMP \Rightarrow IMP \Rightarrow HxR \Rightarrow Hx \Rightarrow X \Rightarrow U$$

Figure 3.8. Sequence of reactions involved in postmortem ATP breakdown. ADP, adenosine diphosphate; AMP, adenosine-5′-phosphate; IMP, inosine-5-phosphate; HxR, inosine; Hx, hypoxanthine; X, xanthine; U, uric acid.

muscle has been very well investigated, and the relative amounts of the different intermediates are generally accepted as fish freshness indicator.

These key freshness indicators such as ornithine, amines, and hypoxanthine, which rapidly build up in fresh seafoods, have been analyzed by various enzymes. These include ornithine carbamoyl transferase, nucleoside phosphorylase, xanthine oxidase, and diamine oxidase for ornithine and amines; and xanthine oxidase for hypoxanthine (Cock et al. 2009). In meats, lactic acid levels tend to increase postmortem, and thus their levels have been monitored as freshness indicators using xanthine oxidase, diamine oxidase, and polyamide oxidase.

In addition to the indirect indicators of food quality or safety described, there are other enzymatic methods for direct detection of contaminating microflora. The latter has gained even greater significance for controlling not only food-borne diseases but also the potential for bioterrorism. The USDA Pathogen Reduction Performance Standards has set limits for the presence of *Salmonella* for all slaughter facilities and raw ground meat products (Alocilja and Radke 2003). Other well-known pathogens recognized as being responsible for food-borne diseases are *Escherichia coli* 0157:H7, *Campylobacter jejuni*, *Listeria monocytogenes, Bacillus cereus, Staphylococcus aureus, Streptococci, etc*. While there are a number of conventional methods for detection of such contaminating microflora or pathogens, they tend to be labor intensive and results are usually not available until after a couple of days. A number of ELISA methods with high sensitivity have since been developed that address this drawback (Croci et al. 2001, Delibato et al. 2006, Salam and Tothill 2009). Some of these ELISA kits (e.g., LOCATE SALMONELLA produced by R-Biopharm) are also commercially available. In their sandwich ELISA method for *Salmonella* detection in precooked chicken, Salam and Tothill (2009) immobilized the capture antibody onto a gold electrode surface, and a second antibody conjugated to horseradish peroxidase was used as the detection system for recognition of captured microbial cells. Detection or binding of the enzyme label is then conducted by an electrochemical system using tetramethylbenzidine dihydrochloride as electron transfer mediator and hydrogen peroxide as substrate.

CONCLUDING REMARKS

It is evident from the foregoing that enzymes play a tremendous role in food analysis and their application for this purpose will likely increase in importance, taking into consideration the developments in the food industry. With consumers becoming increasingly aware of the health implications of foods and the growing demand for functional foods and nutraceuticals, new ingredients are being pervasively introduced into the food supply at a rapid pace. Analysis of these novel ingredients will invariably require novel analytical tools with the sensitivities and specificities that are inherent in enzymes. The convergence of these unique characteristics of enzymes with developments in biotechnology and biosensors certainly make the application of enzymes for food analysis an easier proposition.

Browning Reactions

Marta Corzo-Martínez, Nieves Corzo, Mar Villamiel, and M Dolores del Castillo

Abstract: Browning is one of the most important reactions taking place during food processing and storage. Both, enzymatic and nonenzymatic browning can affect the quality of food in either positive or negative ways, depending on the type of food. Special attention has been paid in this chapter to chemistry of the reaction. During enzymatic browning, phenolic compounds are oxidized to quinones by polyphenol oxidase, this reaction being of particular importance in fruits, vegetables, and seafoods. Nonenzymatic browning is referred to as the Maillard reaction (MR), when it takes place between free amino groups from amino acids, peptides, or proteins and the carbonyl group of reducing sugars. Ascorbic acid, its oxidation products and oxidized lipids can also react *via* MR. It has been also described that aminophospholipids and reducing carbohydrates can interact by MR. Food browning can be also due to degradation of carbohydrates also called caramelization reaction and it is hereby discussed.

INTRODUCTION

Browning reactions are some of the most important phenomena occurring in food during processing and storage. They represent an interesting research for the implications in food stability and technology as well as in nutrition and health. The major groups of reactions leading to browning are enzymatic phenol oxidation and so-called nonenzymatic browning (Manzocco et al. 2001).

ENZYMATIC BROWNING

Enzymatic browning is one of the most important color reactions that affect fruits, vegetables, and seafood. It is catalyzed by the enzyme polyphenol oxidase (PPO; 1,2 benzenediol; oxygen oxidoreductase, EC 1.10.3.1), which is also referred to as phenoloxidase, phenolase, monophenol oxidase, diphenol oxidase (DPO), and tyrosinase. Phenoloxidase enzymes (PPOs) catalyze the oxidation of phenolic constituents to quinones, which finally polymerize to colored melanins (Marshall et al. 2000). Significant advances have been made on biochemistry, molecular biology, and genetics of PPO (Yoruk and Marshall 2003, Queiroz et al. 2008).

Enzymatic browning reactions may affect fruits, vegetables, and seafood in either positive or negative ways. These reactions, for instance, may contribute to the overall acceptability of foods such as tea, coffee, cocoa, and dried fruits (raisins, prunes, dates, and figs). Products of enzymatic browning play key physiological roles. Melanins, produced as a consequence of PPO activity, may exhibit antibacterial, antifungal, anticancer, and antioxidant properties. PPOs impart remarkable physiological functions for the development of aquatic organisms, such as wound healing and hardening of the shell (sclerotization), after molting in insects and in crustaceans such as shrimp and lobster. The mechanism of wound healing in aquatic organisms is similar to

that which occurs in plants in which the compounds produced as a result of the polymerization of quinones, melanins, or melanoidins exhibit both antibacterial and antifungal activities. In addition, enzymatic reactions are considered desirable during fermentation (Fennema 1976). Despite these positive effects, enzymatic browning is considered one of the most devastating reactions for many exotic fruits and vegetables, in particular tropical and subtropical varieties. Enzymatic browning is especially undesirable during processing of fruit slices and juices. Lettuce, other green leafy vegetables; potatoes and other starchy staples, such as sweet potato, breadfruit, and yam; mushrooms; apples; avocados; bananas; grapes; olive (Sciancalepore 1985); peaches; pears (Vamosvigyazo and Nadudvarimarkus 1982); and a variety of other tropical and subtropical fruits and vegetables are susceptible to browning. Crustaceans are also extremely vulnerable to enzymatic browning. Since enzymatic browning can affect color, flavor, and nutritional value of these foods, it can cause tremendous economic losses (Marshall et al. 2000, Queiroz et al. 2008).

A better understanding of the mechanism of enzymatic browning in fruits, vegetables, and seafood; the properties of the enzymes involved; and their substrates and inhibitors may be helpful for controlling browning development, avoiding economic losses, and providing high-quality foods. On the basis of this knowledge, new approaches for the control of enzymatic browning have been proposed. These subjects will be reviewed in this chapter.

PROPERTIES OF PPO

PPO (EC 1.10.3.1; *o*-diphenol oxidoreductase) is an oxidoreductase able to oxidize phenol compounds, employing oxygen as a hydrogen acceptor. The abundance of phenolics in plants may be the reason for naming this enzyme PPO (Marshall et al. 2000). The molecular weight for PPO in plants ranges between 57 and 62 kDa (Hunt et al. 1993, Newman et al. 1993). PPO catalyzes two basic reactions: hydroxylation to the *o*-position adjacent to an existing hydroxyl group of the phenolic substrate (monophenol oxidase activity) and oxidation of diphenol to *o*-benzoquinones (DPO activity; Figure 4.1).

In plants, the ratio of monophenol to DPO activity is usually in the range of 1:40–1:10 (Nicolas et al. 1994). Monophenol oxidase activity is considered more relevant for insect and crustacean systems due to its physiological significance in conjunction with diphenolase activity (Marshall et al. 2000).

PPO is also referred to as tyrosinase to describe both monophenol and DPO activities in either animals or plants. The monophenol oxidase acting in plants is also called cresolase because of its ability to employ cresol as substrate (Marshall et al. 2000). This enzyme is able to metabolize aromatic amines and *o*-aminophenols (Toussaint and Lerch 1987).

The oxidation of diphenolic substrates to quinones in the presence of oxygen is catalyzed by DPO activity (Figure 4.1). The *p*-DPO catalyzed reaction follows a Bi Bi mechanism (Whitaker 1972). Diphenolase activity may be due to two different enzymes: catecholase (catechol oxidase) and laccase (Figure 4.1). Laccase (*p*-DPO,EC 1.10.3.2) is a type of copper-containing PPO. It has the unique ability to oxidize *p*-diphenols. Phenolic substrates, including polyphenols, methoxy-substituted phenols, diamines, and a considerable range of other compounds, serve as substrates for laccase (Marshall et al. 2000). Laccases occur in many phytopathogenic fungi, higher plants (Mayer and Harel 1991), peaches (Harel et al. 1970), and apricots (Dijkstra and Walker 1991).

**Figure 4.1.** Polyphenol oxidase pathway.

Figure 4.2. Simplified mechanism for the hydroxylation and oxidation of diphenol by phenoloxidase.

Catechol oxidase and laccase are distinguishable both on the basis of their phenolic substrates (Figure 4.1), and their inhibitor specificities (Marshall et al. 2000).

Catecholase activity is more important than cresolase action in food because most of the phenolic substrates in food are dihydroxyphenols (Mathew and Parpia 1971).

This bifunctional enzyme, PPO, containing copper in its structure, has been described as an oxygen and four electron-transferring phenol oxidase (Jolley et al. 1974). Figure 4.2 shows a simplified mechanism for the hydroxylation and oxidation of phenols by PPO. Both mechanisms involve the two copper moieties on the PPO.

PPO, active between pH 5 and 7, does not have a very sharp pH optimum. At lower pH values of approximately 3, the enzyme is irreversibly inactivated. Reagents that complex or remove copper from the prosthetic group of the enzyme inactivate the enzyme (Fennema 1976).

SUBSTRATES

Although tyrosine is the major substrate for certain phenolases, other phenolic compounds such as caffeic acid and chlorogenic acid also serve as substrate (Fennema 1976). Structurally, they contain an aromatic ring bearing one or more hydroxyl groups, together with a number of other substituents (Marshall et al. 2000). Structures of common phenolic compounds present in foods are shown in Figure 4.3. Phenolic subtrates of PPO in fruits, vegetables, and seafood are listed in Table 4.1. The substrate specificity of PPO varies in accordance with the source of the enzyme. Phenolic compounds and PPO are, in general, directly responsible for enzymatic browning reactions in damaged fruits during postharvest handling and processing. The relationship of the rate of browning to phenolic content and PPO activity has been reported for various fruits. In addition to serving as PPO substrates, phenolic compounds act as inhibitors of PPOs (Marshall et al. 2000).
Figure 4.3. Structure of common phenols present in foods.

Table 4.1. Phenolic Substrates of PPO in Foods

Source	Phenolic Substrates
Apple	Chlorogenic acid (flesh), catechol, catechin (peel), caffeic acid, 3,4-dihydroxyphenylalanine (DOPA), 3,4-dihydroxy benzoic acid, p-cresol, 4-methyl catechol, leucocyanidin, *p*-coumaric acid, flavonol glycosides
Apricot	Isochlorogenic acid, caffeic acid, 4-methyl catechol, chlorogenic acid, catechin, epicatechin, pyrogallol, catechol, flavonols, *p*-coumaric acid derivatives
Avocado	4-Methyl catechol, dopamine, pyrogallol, catechol, chlorogenic acid, caffeic acid, DOPA
Banana	3,4-Dihydroxyphenylethylamine (Dopamine), leucodelphinidin, leucocyanidin
Cacao	Catechins, leucoanthocyanidins, anthocyanins, complex tannins
Coffee beans	Chlorogenic acid, caffeic acid
Eggplant	Chlorogenic acid, caffeic acid, coumaric acid, cinnamic acid derivatives
Grape	Catechin, chlorogenic acid, catechol, caffeic acid, DOPA, tannins, flavonols, protocatechuic acid, resorcinol, hydroquinone, phenol
Lettuce	Tyrosine, caffeic acid, chlorogenic acid derivatives
Lobster	Tyrosine
Mango	Dopamine-HCl, 4-methyl catechol, caffeic acid, catechol, catechin, chlorogenic acid, tyrosine, DOPA, *p*-cresol
Mushroom	Tyrosine, catechol, DOPA, dopamine, adrenaline, noradrenaline
Peach	Chlorogenic acid, pyrogallol, 4-methyl catechol, catechol, caffeic acid, gallic acid, catechin, dopamine
Pear	Chlorogenic acid, catechol, catechin, caffeic acid, DOPA, 3,4-dihydroxy benzoic acid, *p*-cresol
Plum	Chlorogenic acid, catechin, caffeic acid, catechol, DOPA
Potato	Chlorogenic acid, caffeic acid, catechol, DOPA, *p*-cresol, *p*-hydroxyphenyl propionic acid, *p*-hydroxyphenyl pyruvic acid, *m*-cresol
Shrimp	Tyrosine
Sweet potato	Chlorogenic acid, caffeic acid, caffeylamide
Tea	Flavanols, catechins, tannins, cinnamic acid derivatives

Control of Browning

Enzymatic browning may cause a decrease in the market value of food products originating from plants and crustaceans (Kubo et al. 2000, Perez-Gilabert and García-Carmona 2000, Subaric et al. 2001, Yoruk and Marshall 2003, Queiroz et al. 2008). Processing such as cutting, peeling, and bruising is enough to cause enzymatic browning. The rate of enzymatic browning is governed by the active PPO content of the tissues, the phenolic content of the tissue, and the pH, temperature, and oxygen availability within the tissue. Table 4.2 gives a list of procedures and inhibitors that may be employed for controlling enzymatic browning in foods. A review on conventional and alternative methods to inactivate PPO has been recently published by Queiroz et al. (2008). The inhibition of enzymatic browning generally proceeds via direct inhibition of the PPO, nonenzymatic reduction of o-quinones, and chemical modification or removal of phenolic substrates of PPO. Among all these methods, inhibition of PPO is preferable. According to Marshall et al. (2000), there are six categories of PPO inhibitors applicable to control enzymatic browning: reducing agents, acidulants, chelating agents, complexing agents, enzyme inhibitors, and enzyme treatments. Tyrosinase inhibitors from natural and synthetic sources have been reported by Chang (2009).

Sulfites are the most efficient multifunctional agents in the control of enzymatic browning of foods. The use of sulfites has become increasingly restricted because they can produce adverse reaction in some consumers. L-ascorbic and its stereoisomer erythorbic acid have been considered as the best alternative to sulfite in controlling browning. 4-Hexylresorcinol is also a good substitute to sulfite. Sulphydryl amino acids such as cysteine and reduced glutathione, and inorganic salts like sodium chloride, kojic acid, and oxalic acid (Pilizota and Subaric 1998, Son et al. 2000, Burdock et al. 2001, Yoruk and Marshall 2009) cause an effective decrease in undesirable enzymatic browning in foods. An equivalent of hypotaurine can be an extract of a foodstuff that has a high hypotaurine level such clam, oyster, mussels, squid, octopus, or any combination thereof (Marshall and Schulbach 2009). The application of this naturally occurring compound provides a longer-lasting protection from enzymatic browning in comparison with ascorbic acid or citric acid. On the other hand, taurine addition may provide nutritional benefits to the supplemented foods because of its health-promoting properties.

A decrease in enzymatic browning is achieved by the use of various chelating agents, which either directly form complexes with PPO or react with its substrates. For example, p-cyclodextrin is an inhibitor that reacts with the copper-containing prosthetic group of PPO (Pilizota and Subaric 1998). Crown compounds have potential to reduce the enzymatic browning caused by catechol oxidase because of their ability to complex with copper present in its prosthetic group. The inhibition effect of crown compounds, macrocyclic esters, benzo-18-crown-6 with sorbic acid, and benzo-18-crown-6 with potassium sorbate have been proved for fresh-cut apples (Subaric et al. 2001).

Agro-chemical processes may also be employed for achieving an effective control of enzymatic browning. In vitro studies based on the evaluation of the effect of a range of commonly used pesticides on the activity of purified quince (*Cydonia oblonga* Miller) PPO have indicated that PPO enzyme is competitively inhibited by pesticides such as benomyl, carbaryl, deltamethrine, and parathion methyl (Fattouch et al. 2010). Salinity also affects PPO activity of the fresh-cut vegetables. Increasing salinity conditions may allow fresh-cut vegetables possessing low PPO activity, high phenol content and high antioxidant capacity (Chisari et al. 2010).

Thiol compounds like 2-mercaptoethanol may act as an inhibitor of the polymerization of o-quinone and as a reductant involved in the conversion of o-quinone to o-dihydroxyphenol (Negishi and Ozawa 2000).

Because of safety regulations and the consumer's demand for natural food additives, much research has been devoted to the search for natural and safe anti-browning agents. Honey (Chen et al. 2000, Gacche et al. 2009); papaya latex extract (De Rigal et al. 2001); banana leaf extract either alone or in combination with ascorbic acid and 4-hexylresorcinol (Kaur and Kapoor 2000); onion juice (Hosoda and Iwahashi 2002); onion oil (Hosoda et al. 2003); onion extracts (Kim et al. 2005); onion by-products (residues and surpluses; Roldan et al. 2008); rice bran extract (Boonsiripiphat and Theerakulkait 2009); solutions containing citric acid, calcium chloride, and garlic extract (Ihl et al. 2003); Maillard reaction products (MRPs) obtained by heating of hexoses in presence of cystein or glutathione (Billaud et al. 2003, 2004); N-acetylcysteine and glutathione (Rojas-Grau et al. 2008); resveratrol, a natural ingredient of red wine possessing several biological activities, and other hydroxystilbene compounds, including its analogous oxyresveratrol (Kim et al. 2002); and hexanal (Corbo et al. 2000), Brassicacaea processing water (Zocca et al. 2010); and chitosan (Martin-Diana et al. 2009) are some examples of natural inhibitors of PPO. In most cases, the inhibiting activity of plant extract is due to more than one component. Moreover, a good control of enzymatic browning may involve endogenous antioxidants (Mdluli and Owusu-Apenten 2003).

Regulation of the biosynthesis of polyphenols (Hisaminato et al. 2001) and the use of commercial glucose oxidase–catalase enzyme system for oxygen removal (Parpinello et al. 2002) have been described as essential and effective ways of controlling enzymatic browning.

Commonly, an effective control of enzymatic browning can be achieved by a combination of anti-browning agents (Zocca et al. 2010). A typical combination might consist of a chemical reducing agent such as ascorbic acid, an acidulant such as citric acid, and a chelating agent like EDTA (Marshall et al. 2000)

A great emphasis is put on research to develop methods for preventing enzymatic browning especially in fresh-cut (minimally processed) fruits and vegetables. The most efficient way to control this problem is the combination of physical and chemical methods, by avoiding the use of more severe individual treatments, which could harm the appearance and texture of vegetables. Technological processing, including microwave blanching either alone or combined with chemical anti-browning agents (Severini et al. 2001, Premakumar and Khurduya 2002, Yadav et al. 2008, Guan and Fan 2010); CO_2 treatments (Rocha and

Table 4.2. Inhibitors and Processes Employed in the Prevention of Enzymic Browning

Inhibition Targeted Toward the Enzyme		Inhibition Targeted Toward the Substrate		Inhibition Targeted Toward the Products
Processing	Enzymes Inhibitors	Removal of Oxygen	Removal of Phenols

Morais 2001, Kaaber et al. 2002, Valverde et al. 2010); pretreatments employing sodium or calcium chloride and lactic acid followed by conventional blanching (Severini et al. 2003); combination of sodium chlorite and calcium propionate (Guan and Fan 2010); high-pressure treatments combined with thermal treatments and chemical anti-browning agents such as ascorbic acid (Prestamo et al. 2000, Ballestra et al. 2002) or natural anti-browning agents like pineapple juice (Perera et al. 2010); and UV-C light treatment of fresh-cut vegetables under nonthermal conditions (Manzocco et al. 2009) have been employed to prevent enzymatic browning in foods.

The use of edible coating from whey protein isolate-beeswax (Perez-Gago et al. 2003); edible coatings enriched with natural plant extracts (Ponce et al. 2008); oxygen-controlled atmospheres (Jacxsens et al. 2001, Soliva-Fortuny et al. 2001, Duan et al. 2009), and the use of active films (Endo et al. 2008) seem to improve the shelf life of foods by inhibition of PPO.

Biotechnological approaches may be also employed for the control of PPO (Rodov 2007). Transgenic fruits carrying an antisense PPO gene show a reduction in the amount and activity of PPO, and the browning potential of transgenic lines are reduced compared with the non-transgenic ones (Murata et al. 2000, Murata et al. 2001). These procedures may be used to prevent enzymatic browning in a wide variety of food crops without the application of various food additives (Coetzer et al. 2001).

NONENZYMATIC BROWNING

THE MAILLARD REACTION

Nonenzymatic browning is the most complex reaction in food chemistry because a large number of food components are able to participate in the reaction through different pathways, giving rise to a complex mixture of products (Olano and Martínez-Castro 2004). It is referred to as the Maillard reaction when it takes place between free amino groups from amino acids, peptides, or proteins and the carbonyl group of a reducing sugar. The

historical perspective showed by Finot (2005) shows the great importance of Maillard reaction on food science and nutrition.

The Maillard reaction is one of the main reactions causing deterioration of proteins during processing and storage of foods. This reaction can promote nutritional changes such as loss of nutritional quality (attributed to the destruction of essential amino acids) or reduction of protein digestibility and amino acid availability (Malec et al. 2002).

The Maillard reaction covers a whole range of complex transformations (Figure 4.4) that produces a large number of the so-called Maillard reaction products (MRPs) such as aroma compounds, ultraviolet absorbing intermediates, and dark-brown polymeric compounds named melanoidins (Kim and Lee 2008a). It can be divided into three major phases: the early, intermediate, and advanced stages. The early stage (Figure 4.5) consists of the condensation of primary amino groups of amino acids, peptides, or proteins with the carbonyl group of reducing sugars (aldose), with loss of a molecule of water, leading, via formation of a Schiff's base and Amadori rearrangement, to the so-called Amadori product (1-amino-1-deoxi-2-ketose), a relatively stable intermediate (Feather et al. 1995). The Heyns compound is the analogous compound when a ketose is the starting sugar. In many foods, the ε-amino group of the lysine residues of proteins is the most important source of reactive amino groups, but because of blockage, these lysine residues are not available for digestion, and consequently the nutritive value decreases (Brands and van Boekel 2001, Machiels and Istasse 2002). Amadori compounds are precursors of numerous compounds that are important in the formation of characteristic flavors, aromas, and brown polymers. They are formed before the occurrence of sensory changes; therefore, their determination provides a very sensitive indicator for early detection of quality changes caused by the Maillard reaction (Olano and Martínez-Castro 2004).

The intermediate stage leads to breakdown of Amadori compounds (or other products related to the Schiff's base) and the formation of degradation products, reactive intermediates (3-deoxyglucosone), and volatile compounds (formation of flavor).
Figure 4.4. Scheme of different stages of Maillard reaction (Hodge 1953, Ames 1990).

The 3-deoxyglucosone participates in cross-linking of proteins at much faster rates than glucose itself, and further degradation leads to two known advanced products: 5-hydroxymethyl-2-furaldehyde and pyraline (Feather et al. 1995).

The final stage is characterized by the production of nitrogen-containing brown polymers and copolymers known as melanoidins (Badoud et al. 1995). The structure of melanoidins is largely unknown, but in the last few years, more data became available. In particular, it was shown that they can have a different structure according to the starting material. Melanoidins have been described as low-molecular weight (LMW) colored substances that are able to cross-link proteins via ε-amino groups of lysine or arginine to produce high-molecular weight (HMW) colored melanoidins. Also, it has been postulated that they are polymers consisting of repeating units of furans and/or pyrroles, formed during the advanced stages of the Maillard reaction and linked by polycondensation reactions (Martins and van Boekel 2003). Chemical structure of melanoidins can be mainly formed by a carbohydrate skeleton with few unsaturated rings and small nitrogen components; in other cases, they can have a protein structure linked to small chromophores (Borrelli and Fogliano 2005).

In foods, predominantly glucose, fructose, maltose, lactose, and to some extent reducing pentoses are involved with amino acids and proteins in forming fructoselysine, lactuloselysine or maltuloselysine. In general, primary amines are more impor-

tant than secondary ones, because the concentration of primary amino acids in foods is usually higher than that of secondary amino acids (an exception is the high amount of proline in malt and corn products) (Ledl 1990).

Factors Affecting Maillard Reaction

The rate of the Maillard reaction and the nature of the products formed depend on the chemical environment of food, including water activity (a_w), pH, and chemical composition of the food system, temperature being the most important factor (Carabasa-Giribert and Ibarz-Ribas 2000). In order to predict the extent of chemical reactions in processed foods, knowledge of kinetic reactions is necessary to optimize the processing conditions. Since foods are complex matrices, these kinetic studies are often carried out using model systems in which sugars and amino acids react under simplified conditions. Model system studies may provide guidance regarding the directions in which to modify the food process and to find out which reactants may produce specific effects of the Maillard reaction (Lingnert 1990).

The reaction rate is significantly affected by the pH of the system; it generally increases with pH (Namiki et al. 1993, Ajandouz and Puigserver 1999). Bell (1997) studied the effect of buffer type and concentration on initial degradation of amino acids and formation of brown pigments in model systems of glycine and glucose that are stored for long periods at 25°C. The
Figure 4.5. Initial stages of the Maillard reaction and acrylamide formation (Friedman 2003).

loss of glycine was faster at high phosphate buffer concentration (Figure 4.6), showing its catalytic effect on the Maillard reaction. The effects of salt concentration on the rates of browning reaction of amino acid, peptides, and proteins have also been studied by Yamaguchi et al. (2009). High concentration of sodium chloride retarded the reaction rate of glucose with amino acids but did not change the browning rate of glucose with peptides.

The type of reducing sugar has a great influence on Maillard reaction development. Pentoses (e.g., ribose) react more readily than hexoses (e.g., glucose), which, in turn, are more reactive than disaccharides (e.g., lactose; Ames 1990). A study

on brown development (absorbance at 420 nm) in a heated model of fructose and lysine showed that browning was higher than in model systems with glucose (Ajandouz et al. 2001). A study using heated galactose/glycine model systems found that the rate of color development in Maillard reaction followed first-order kinetics on galactose concentration (Liu et al. 2008). The effects of tagatose on the Maillard reaction has been also investigated in aqueous model systems containing various sugars (glucose, galactose, fructose, and tagatose) and amino acids through volatile Maillard products determination (Cho et al. 2010).
Figure 4.6. Effect of phosphate buffer concentration on the loss of glycine in 0.1 M glucose/glycine solutions at pH 7 and 25°C. (Bell 1997).

been studied (Carabasa-Giribert and Ibarz-Ribas 2000, Mundt and Wedzicha 2003). The reaction between free amino acids and carbonyl compounds has been studied extensively; however, only a minor part of the Maillard reaction studies focused on peptides and proteins. Van Lancker et al. (2010) have studied the formation of flavor compounds from model systems of lysine-containing peptides and glucose, methylglyoxal, and glyoxal. The main compounds found were pyrazines, which contribute significantly to the roasted aroma of many heated food products.

Studies on the effect of time and temperature of treatment on the Maillard reaction development have also been conducted in different model systems, and it has been shown that an increase in temperature increases the rate of Maillard browning (Martins and van Boekel 2003, Ryu et al. 2003).

Concentration and ratio of reducing sugar to amino acid have a significant impact on the reaction. Browning reaction increased with increasing glycine to glucose ratios in the range 0.1:1–5:1 in a model orange juice system at 65°C (Wolfrom et al. 1974). In a model system of intermediate moisture ($a_w = 0.52$), Warmbier et al. (1976) observed an increase of browning reaction rate when the molar ratio of glucose:lysine increased from 0.5:1 to 3.0:1.

a_w is another important factor influencing the Maillard reaction development; thus, this reaction occurs less readily in foods with high a_w value due to the reactants are diluted. However, at low a_w values, the mobility of reactants is limited despite their presence at increased concentrations (Ames 1990). Numerous studies have demonstrated a browning rate maximum at a_w value from 0.5 to 0.8 in dried and intermediate-moisture foods (Warmbier et al. 1976, Tsai et al. 1991, Buera and Karel

Participation of amino acids in the Maillard reaction is variable; thus lysine was the most reactive amino acid (Figure 4.7) in the heated model system of glucose and lysine, threonine, and methionine in phosphate buffer at different pH values (4–12) (Ajandouz and Puigserver 1999). The influence of type of amino acid and sugar in the Maillard reaction development has also

Figure 4.7. Brown color development in aqueous solutions containing glucose alone or in the presence of an essential amino acid when heated to 100°C at pH 7.5 as a function of time (Ajandouz and Puigserver 1999).

1995). The effect of a_w (0.33, 0.43, 0.52, 0.69, 0.85, and 0.98) on the rate of loss of lysine by mild heat treatment or during storage of milk powder was only significant at high a_w values (Pereyra-Gonzales et al. 2010).

Because of the complex composition of foods, it is unlikely that Maillard reaction involves only single compound (mono- or disaccharides and amino acids). For this reason, several studies on factors (pH, T, a_w) that influence the Maillard reaction development have been carried out using more complex model systems: heated starch–glucose–lysine systems (Bates et al. 1998), milk resembling model systems (lactose or glucose–caseinate systems) (Morales and van Boekel 1998), and lactose–casein model system (Malec et al. 2002, Jiménez-Castaño et al. 2005). Brands and van Boekel (2001) studied the Maillard reaction using heated monosaccharide (glucose, galactose, fructose, and tagatose)–casein model systems in order to quantify and identify the main reaction products and to establish the reaction pathways.

Studies on mechanisms of degradation, via the Maillard reaction, of oligosaccharides in a model system with glycine were performed by Hollnagel and Kroh (2000, 2002). The reactivity of di- and trisaccharides under quasi water-free conditions decreased in comparison to that of glucose due to the increasing degree of polymerization.

Study of Maillard Reaction in Foods

During food processing, the Maillard reaction produces desirable and undesirable effects. Processing such as baking, frying, and roasting are based on the Maillard reaction for flavor, aroma, and color formation (Lingnert 1990). Maillard browning may be desirable during manufacture of meat, coffee, tea, chocolate, nuts, potato chips, crackers, and beer and in toasting and baking bread (Weenen 1998, Burdulu and Karadeniz 2003). In other processes such as pasteurization, sterilization, drying, and storage, the Maillard reaction often causes detrimental nutritional (lysine damage) and organoleptic changes (Lingnert 1990). Available lysine determination methods has been used to assess the Maillard reaction extension in different types of foods: breads, breakfast cereals, pasta, infant formula (Erbersdobler and Hupe 1991), dried milks (El and Kavas 1997), heated milks (Ferrer et al. 2003), and infant cereals (Ramírez-Jimenez et al. 2004).

Sensory changes in foods due to the Maillard reaction have been studied in a wide range of foods, including honey (Gonzales et al. 1999), apple juice concentrate (Burdulu and Karadeniz 2003), and white chocolate (Vercet 2003).

Other types of undesirable effects produced in processed foods by the Maillard reaction may include the formation of mutagenic and cancerogenic compounds (Lingnert 1990, Chevalier et al. 2001). Frying or grilling of meat and fish may generate low (ppb) levels of mutagenic/carcinogenic heterocyclic amines via the Maillard reaction. The formation of these compounds depends on cooking temperature and time, cooking technique and equipment, heat, mass transport, and/or chemical parameters. Tareke et al. (2002) reported their findings on the carcinogen acrylamide in a range of cooked foods. Moderate levels of acrylamide (5–50 μg/kg) were measured in heated protein-rich foods, and higher levels (150–4000 μg/kg) were measured in carbohydrate-rich food, such as potato, beet root, certain heated commercial potato products, and crisp bread. Ahn et al. (2002) tested different types of commercial foods and some foods heated under home cooking conditions, and they observed that acrylamide was absent in raw or boiled foods, but it was present at significant levels in fried, grilled, baked, and toasted foods. Although the mechanism of acrylamide formation in heated foods is not yet clear, several authors have put forth the hypothesis that the reaction of asparagine (Figure 4.5), a major amino acid of potatoes and cereals, with reducing sugars (glucose, fructose) via the Maillard reaction, at temperatures above 120°C, could be the pathway (Mottram et al. 2002, Weiβhaar and Gutsche 2002, Friedman 2003, Yaylayan and Stadler 2005). Other amino acids have also been found to produce low amounts of acrylamide, including alanine, arginine, aspartic acid, cysteine, glutamine, threonine, valine, and methionine (Stadler et al. 2002, Tateo et al. 2007). Over the years, much work have been done to study the factor influencing the acrylamide formation during processing (Granda and Moreira 2005, Gökmen and Senyuva 2006, Tateo et al. 2007, Burch et al. 2008, Jom et al. 2008, Carrieri et al. 2010), the mechanism of acrylamide formation (Elmore et al. 2005, Hamlet et al. 2008, Zamora et al. 2010), the development of robust and sensitive analytical methods that provide reliable data in the different food categories (Zhang et al. 2005, Kaplan et al. 2009, Preston et al. 2009), and the content in different processed foods (Bermudo et al. 2006, Tateo et al. 2007, Burch et al. 2008, EFSA 2010). On the basis of the large number of existing studies, the International Agency for Research on Cancer (IARC 1994) has classified acrylamide as "probably carcinogenic" to humans. Currently, researchers are looking around for other strategies to obtain finished foods without acrylamide. In this sense, Anese et al. (2010) have proposed the possibility to remove acrylamide from foods by exploiting its chemical and physical properties. Thus, processed foods were subjected to vacuum treatments at different combinations of pressure, temperature, and time. Removal of acrylamide was achieved only in samples previously hydrated at a_w values higher than 0.83, and maximum removed amount was between 5 and 15 minutes of vacuum treatment at 6.67 Pa and 60°C.

Beneficial properties of Maillard products have also been described. Resultant products of the reaction of different amino acid and sugar model systems presented different properties: antimutagenic (Yen and Tsai 1993); antimicrobial (Chevalier et al. 2001, Rufián-Henares and Morales 2007) and antioxidative (Manzocco et al. 2001, Wagner et al. 2002, Rufián-Henares and Morales 2007). In foods, antioxidant properties of MRPs have been found in honey (Antony et al. 2000) and in tomato purees (Anese et al. 2002). Rufián-Henares and de la Cueva (2009) found antimicrobial activity of coffee melanoidins against different pathogenic bacteria.

On the other hand, the Maillard reaction is one of the safest and most efficient methods to generate new functional proteins with great potential as novel ingredients. Miralles et al. (2007) investigated the occurrence of the Maillard reaction between β-lactoglobulin and a LMW chitosan. Under the studied conditions, MRPs originated improved antibacterial activity against

Escherichia coli and emulsifying properties. Recently, Corzo-Martínez et al. (2010) observed an improvement in gelling and viscosity properties of glycosylated sodium caseinate via Maillard reaction with lactose and galactose.

Control of the Maillard Reaction in Foods

For a food technologist, one of the most important objectives must be to limit nutritional damage of food during processing. In this sense, many studies have been performed and found useful heat-induced markers derived from the Maillard reaction, and most of them have been proposed to control and check the heat treatments and/or storage of foods. There are many indicators of different stages of the Maillard reaction, but this review cites one of the most recent indicators proposed to control early stages of this reaction during food processing: the 2-furoylmethyl amino acids as an indirect measure of the Amadori compound formation.

Determination of the level of Amadori compounds provides a very sensitive indicator for early detection (before detrimental changes occur) of quality changes caused by the Maillard reaction as well as for retrospective assessment of the heat treatment or storage conditions to which a product has been subjected (del Castillo et al. 1999, Olano and Martínez-Castro 2004).

Evaluating for Amadori compounds can be carried out through furosine [ε-*N*-(2-furoylmethyl)-L-lysine] measurement. This amino acid is formed by acid hydrolysis of the Amadori compound ε-*N*-(1-deoxy-D-fructosyl)-L-lysine. It is considered a useful indicator of the damage in processed foods or foods stored for long periods: milks (Resmini et al. 1990, Villamiel et al. 1999); eggs (Hidalgo et al. 1995); cheese (Villamiel et al. 2000); honey (Villamiel et al. 2001, Morales et al. 2009); infant formula (Guerra-Hernandez et al. 2002, Cattaneo et al. 2009); milk-cereal-based baby foods (Bosch et al. 2008); jams and fruit-based infant foods (Rada-Mendoza et al. 2002); fresh filled pasta (Zardetto et al. 2003); prebaked breads (Ruiz et al. 2004), cookies, crackers, and breakfast cereals (Rada-Mendoza et al. 2004, Gökmen et al. 2008); fiber-enriched breakfast cereals (Delgado-Andrade et al. 2007); flour used for formulations of cereal-based-products (Rufián-Henares et al. 2009); and sauces and sauces-treated foods (Chao et al. 2009). Erbersdobler and Somoza (2007) have written an interesting review on 40 years of use of furosine as a reliable indicator of thermal damage in foods.

In the case of foods containing free amino acids, free Amadori compounds can be present, and acid hydrolysis gives rise to the formation of the corresponding 2-furoylmethyl derivatives. For the first time, 2-furoylmethyl derivatives of different amino acids (arginine, asparagine, proline, alanine, glutamic acid, and Υ-amino butyric acid) have been detected and have been used as indicators of the early stages of the Maillard reaction in stored dehydrated orange juices (del Castillo et al. 1999). These compounds were proposed as indicators to evaluate quality changes either during processing or during subsequent storage. Later, most of these compounds were also detected in different foods: commercial orange juices (del Castillo et al. 2000), processed tomato products (Sanz et al. 2000), dehydrated fruits (Sanz et al. 2001) and carrots (Soria et al. 2010), commercial honey samples (Sanz et al. 2003), and infant formula (Penndorf et al. 2007).

CARAMELIZATION

During nonenzymatic browning of foods, various degradation products are formed via caramelization of carbohydrates, without amine participation (Ajandouz and Puigserver 1999, Ajandouz et al. 2001). Caramelization occurs when surfaces are heated strongly (e.g., during baking and roasting), during the processing of foods with high sugar content (e.g., jams and certain fruit juices), or in wine production (Kroh 1994). Caramelization is used to obtain caramel-like flavor and/or development of brown color in certain types of foods. Caramel flavoring and coloring, produced from sugar with different catalysts, is one of the most widely used additives in the food industry. However, caramelization is not always a desirable reaction because of the possible formation of mutagenic compounds (Tomasik et al. 1989) and the excessive changes in the sensory attributes that could affect the quality of certain foods.

More recently, Kitts et al. (2006) also observed the clastogenic activity of caramelized sucrose, this property being mainly due to the volatile and nonvolatile compounds of LMW derived from sucrose caramelization.

Caramelization is catalyzed under acidic or alkaline conditions (Namiki 1988) and many of the products formed are similar to those resulting from the Maillard reaction.

Caramelization of carbohydrates starts with the opening of the hemiacetal ring followed by enolization, which proceeds via acid- and base-catalyzed mechanisms, leading to the formation of isomeric carbohydrates (Figure 4.8). The interconversion of sugars through their enediols increases with increasing pH and is called the Lobry de Bruyn-Alberda van Ekenstein transformation (Kroh 1994). In acid media, low amounts of isomeric carbohydrates are formed; however, dehydration is favored, leading to furaldehyde compounds: 5-(hydroxymethyl)-2-furaldehyde (HMF) from hexoses (Figure 4.9) and 2-furaldehyde from pentoses. With unbuffered acids as catalysts, higher yields of HMF are produced from fructose than from glucose. Also, only the fructose moiety of sucrose is largely converted to HMF under unbuffered conditions, which produce the highest yields. The enolization of glucose can be greatly increased in buffered acidic solutions. Thus, higher yields of HMF are produced from

Figure 4.8. The Lobry de Bruyn-Alberda van Ekenstein transformation.
Figure 4.9. 1,2 Enolization and formation of hydroxymethyl furfural (HMF).

glucose and sucrose when a combination of phosphoric acid and pyridine is used as catalysts than when phosphoric acid is used alone (Fennema 1976).

In alkaline media, dehydration reactions are slower than in neutral or acid media, but fragmentation products such as acetol, acetoin, and diacetyl are detected. In the presence of oxygen, oxidative fission takes place, and formic, acetic, and other organic acids are also formed. All of these compounds react to produce brown polymers and flavor compounds (Olano and Martínez-Castro 2004).

In general, caramelization products (CPs) consist of volatile and nonvolatile (90–95%) fractions of LMWs and HMWs that vary depending on temperature, pH, duration of heating, and starting material (Defaye et al. 2000). Although it is known that caramelization is favored at temperatures higher than 120°C and at a pH greater than 9 and less than 3, depending on the composition of the system (pH and type of sugar), caramelization reactions may also play an important role in color formation in systems heated at lower temperatures. Thus, some studies have been conducted at the temperatures of accelerated storage conditions (45–65°C) and pH values from 4 to 6 (Buera et al. 1987a, 1987b). These authors studied the changes of color due to caramelization of fructose, xylose, glucose, maltose, lactose, and sucrose in model systems of 0.9 a_w and found that fructose and xylose browned much more rapidly than other sugars and lowering of pH inhibited caramelization browning of sugar solutions.

In a study on the kinetics of caramelization of several monosaccharides and disaccharides, Diaz and Clotet (1995) found that at temperatures of 75–95°C, browning increased rapidly with time and to a higher final value, with increasing temperature, this effect being more marked in the monosaccharides than in the disaccharides. In all sugars studied, increase of browning was greater at $a_w = 1$ than at a $_w = 0.75$. Likewise, results of a more recent study on the kinetics of browning development showed that at temperatures of 75–95°C and pH 3.0, color development increased linearly with a first-order kinetics on fructose concentration (Chen et al. 2009).

The effect of sugars, temperature, and pH on caramelization was evaluated by Park et al. (1998). Reaction rate was highest with fructose, followed by sucrose. As reaction temperature in-creased from 80°C to 110°C, reaction rate was greatly increased. With respect to pH, the optimum value for caramelization was 10. In agreement with this, more recently, Kim and Lee (2008b) reported that degradation/enolization of sugars rapidly increased at a high alkaline pH (10.0–12.0) and with increasing heating times, fructose being degraded/enolized more rapidly than glucose.

Although most studies on caramelization have been conducted in model systems of mono- and disaccharides, a number of real food systems contain oligosaccharides or even polymeric saccharides; therefore, it is also of great interest to know the contribution of these carbohydrates to the flavor and color of foods. Kroh et al. (1996) reported the breakdown of oligo- and polysaccharides to nonvolatile reaction products. Homoki-Farkas et al. (1997) studied, through an intermediate compound (methylglyoxal), the caramelization of glucose, dextrin 15, and starch in aqueous solutions at 170°C under different periods of time. The highest formation of methylglyoxal was in glucose and the lowest in starch systems. The authors attributed the differences to the number of reducing end groups. In the case of glucose, when all molecules are degraded, the concentration of methylglyoxal reached a maximum and began to transform, yielding LMW and HMW color compounds. Hollnagel and Kroh (2000, 2002) investigated the degradation of malto-oligosaccharides at 100°C through α-dicarbonyl compounds such as 1,4-dideoxyhexosulose, and they found that this compound is a reactive intermediate and precursor of various heterocyclic volatile compounds that contribute to caramel flavor and color. More recently, it has been observed that galactomannans of roasted coffee infusions are HMW supports of LMW brown compounds derived from caramelization reactions (Nunes et al. 2006).

Perhaps, as mentioned above, the most striking feature of caramelization is its contribution to the color and flavor of certain food products under controlled conditions. In addition, it is necessary to consider other positive characteristics of this reaction, such as the antioxidant activity of the CPs. This property has been found to vary depending on temperature, pH, duration of heating, and starting material, main variables affecting the caramelization kinetics. Thus, several studies (Benjakul et al. 2005, Phongkanpai et al. 2006, Kim and Lee 2008b) have

reported that antioxidative activity of CPs from different sugars (fructose, glucose, ribose, and xylose) increased with increasing pH levels (7.0–12.0), heating temperature (80–180°C), and heating time (0–180 minutes). The CPs from fructose exhibited the highest antioxidant activity as evidenced by the greatest scavenging effect and reducing power. In addition, this increase in antioxidative activity was coincidental with the browning development and intermediate formation. This suggested that both colorless intermediates, such as reductones and dehydroreductones, produced in the earlier stages of the caramelization, (Rhee and Kim 1975) and HMW and colored pigments, produced in the advanced stages, might play an important role in the antioxidant activity of CPs (Kirigaya et al. 1968)

In addition, the effect of caramelized sugars on enzymatic browning has been studied by several authors. Thus, Pitotti et al. (1995) reported that the anti-browning effect of some CPs is in part related to their reducing power. Lee and Lee (1997) obtained CPs by heating a sucrose solution at 200°C under various conditions to study the inhibitory activity of these products on enzymatic browning. The reducing power of CPs and their inhibitory effect on enzymatic browning increased with prolonged heating and with increased amounts of CPs. Caramelization was investigated in solutions of fructose, glucose, and sucrose heated at temperatures up to 200°C for 15–180 minutes. Browning intensity increased with heating time and temperature. The effect of the caramelized products on PPO was evaluated, and the greatest PPO inhibitory effect was demonstrated by sucrose solution heated to 200°C for 60 minutes (Lee and Han 2001). More recently, Billaud et al. (2003) found CPS from hexoses with mild inhibitory effects on PPO, particularly after prolonged heating at 90°C.

Antioxidative activity of CPs from higher molecular weight carbohydrates has also been reported. Thus, Mesa et al. (2008), in a study on antioxidant properties of hydrolyzates of soy protein-fructooligosaccharide glycation systems, found that the most neoantioxidants products are able to prevent LDL oxidation and to scavenge peroxyl-alkyl radicals derived from the thermal degradation (95°C for 1 hour) of fructooligosaccharides rather than from the Maillard reaction.

ASCORBIC ACID BROWNING

Ascorbic acid (vitamin C) plays an important role in human nutrition as well as in food processing (Chauhan et al. 1998). Its key effect as an inhibitor of enzymatic browning has been previously discussed in this chapter.

Browning of ascorbic acid can be briefly defined as the thermal decomposition of ascorbic acid under both aerobic and anaerobic conditions, by oxidative or non-oxidative mechanisms, either in the presence or absence of amino compounds (Wedzicha 1984).

Nonenzymatic browning is one of the main reasons for the loss of commercial value in citrus products (Manso et al. 2001). These damages, degradation of ascorbic acid followed by browning, also concern noncitrus foods such as asparagus, broccoli, cauliflower, peas, potatoes, spinach, apples, green beans, apricots, melons, strawberries, corn, and dehydrated fruits (Belitz and Grosch 1997).

Pathway of Ascorbic Acid Browning

The exact route of ascorbic acid degradation is highly variable and dependent upon the particular system. Factors that can influence the nature of the degradation mechanism include temperature, salt and sugar concentration, pH, oxygen, enzymes, metal catalysts, amino acids, oxidants or reductants, initial concentration of ascorbic acid, and the ratio of ascorbic acid to dehydroascorbic acid (DHAA; Fennema 1976).

Figure 4.10 shows a simplified scheme of ascorbic acid degradation. When oxygen is present in the system, ascorbic acid is degraded primarily to DHAA. DHAA is not stable and spontaneously converts to 2,3-diketo-L-gulonic acid (Lee and Nagy 1996). Under anaerobic conditions, ascorbic acid undergoes the generation of diketogulonic acid via its keto tautomer, followed by β elimination at C-4 from this compound and decarboxylation to give rise to 3-deoxypentosone, which is further degraded to furfural. Under aerobic conditions, xylosone is produced by simple decarboxylation of diketogulonic acid and that is later converted to reductones. In the presence of amino acids, ascorbic acid, DHAA, and their oxidation products furfural, reductones, and 3-deoxypentosone may contribute to the browning of foods by means of a Maillard-type reaction (Fennema 1976, Belitz and Grosch 1997). Formation of Maillard-type products has been detected both in model systems and foods containing ascorbic acid (Kacem et al. 1987, Ziderman et al. 1989, Loschner et al. 1990, 1991, Mölnar-Perl and Friedman 1990, Yin and Brunk 1991, Davies and Wedzicha 1992, 1994, Pischetsrieder et al. 1995, 1997, Rogacheva et al. 1995, Koseki et al. 2001).

The presence of metals, especially Cu^{2+} and Fe^{3+}, causes great losses of vitamin C. Catalyzed oxidation goes faster than the spontaneous oxidation. Anaerobic degradation, which occurs slower than uncatalyzed oxidation, is maximum at pH 4 and minimum at pH 2 (Belitz and Grosch 1997).

Ascorbic acid oxidation is nonenzymatic in nature, but oxidation of ascorbic acid is sometimes catalyzed by enzymes. Ascorbic acid oxidase is a copper-containing enzyme that catalyzes oxidation of vitamin C. The reaction is catalyzed by copper ions. The enzymatic oxidation of ascorbic acid is important in the citrus industry. Reaction takes place mainly during extraction of juices. Therefore, it becomes important to inhibit the ascorbic oxidase by holding juices for only short times and at low temperatures during the blending stage, by de-aerating the juice to remove oxygen, and finally by pasteurizing the juice to inactivate the oxidizing enzymes.

Enzymatic oxidation has also been proposed as a mechanism for the destruction of ascorbic acid in orange peels during the preparation of marmalade. Boiling the grated peel in water substantially reduces the loss of ascorbic acid (Fennema 1976).

Tyrosinase (PPO) may also possess ascorbic oxidase activity. A possible role of the ascorbic acid-PPO system in the browning of pears has been proposed (Espin et al. 2000).

In citrus juices, nonenzymatic browning is from reactions of sugars, amino acids, and ascorbic acid (Manso et al. 2001). In freshly produced commercial juice, filled into TetraBrik cartons, it has been demonstrated that nonenzymatic browning was mainly due to carbonyl compounds formed from L-ascorbic acid
Figure 4.10. Pathways of ascorbic acid degradation (solid line, anaerobic route; dashed line, aerobic route).

degradation. Contribution from sugar-amine reactions is negligible, as evident from the constant total sugar content of degraded samples. The presence of amino acids and possibly other amino compounds enhance browning (Roig et al. 1999).

Both oxidative and nonoxidative degradation pathways are operative during storage of citrus juices. Since large quantities of DHAA are present in citrus juices, it can be speculated that the oxidative pathway must be dominant (Lee and Nagy 1996, Rojas and Gerschenson 1997a). A significant relationship between DHAA and browning of citrus juice has been found (Kurata et al. 1973, Sawamura et al. 1991, Sawamura et al. 1994). The rate of non-oxidative loss of ascorbic acid is often one-tenth or up to one-thousandth the rate of loss under aerobic conditions (Lee and Nagy 1996). In aseptically packed orange juice, the aerobic reaction dominates first and it is fairly rapid, while the anaerobic reaction dominates later and it is quite slow (Nagy and Smoot 1977, Tannenbaum 1976). A good prediction of ascorbic acid degradation and the evolution of the browning index of orange juice stored under anaerobic conditions at 20–45°C may be performed by employing the Weibull model (Manso et al. 2001).

Furfural, which is formed during anaerobic degradation of ascorbic acid, has a significant relationship to browning (Lee and Nagy 1988); its formation has been suggested as an adequate index for predicting storage temperature abuse in orange juice concentrates and as a quality deterioration indicator in single-strength juice (Lee and Nagy 1996). However, furfural is a very reactive aldehyde that forms and decomposes simultaneously; therefore, it would be more difficult to use as an index for predicting quality changes in citrus products (Fennema 1976). In general, ascorbic acid would be a better early indicator of quality.

Control of Ascorbic Acid Browning

Sulfites (Wedzicha and Mcweeny 1974, Wedzicha and Imeson 1977), thiols compounds (Naim et al. 1997), maltilol (Koseki et al. 2001), sugars, and sorbitol (Rojas and Gerschenson 1997b) may be effective in suppressing ascorbic acid browning. Doses to apply these compounds highly depend on factors such as concentration of inhibitors and temperatures. L-Cysteine and sodium sulfite may suppress or accelerate ascorbic acid browning as a function of their concentration (Sawamura et al. 2000). Glucose, sucrose, and sorbitol protect L-ascorbic acid from destruction at low temperatures (23°C, 33°C, and 45°C), while at higher temperatures (70°C, 80°C, and 90°C), compounds with active carbonyls promoted ascorbic acid destruction. Sodium bisulfite was only significant in producing inhibition at lower temperature ranges (23°C, 33°C, and 45°C; Rojas and Gerschenson 1997b).

Although the stability of ascorbic acid generally increases as the temperature of the food is lowered, certain investigations have indicated that there may be an accelerated loss on freezing or frozen storage. However, in general, the largest losses for noncitrus foods will occur during heating (Fennema 1976).

The rapid removal of oxygen from the packages is an important factor in sustaining a higher concentration of ascorbic acid and lower browning of citrus juices over long-term storage. The extent of browning may be reduced by packing in oxygen scavenging film (Zerdin et al. 2003).

Modified-atmosphere packages (Howard and Hernandez-Brenes 1998), microwave heating (Villamiel et al. 1998, Howard et al. 1999), ultrasound-assisted thermal processing (Zenker et al. 2003), pulsed electric field processing (Min et al. 2003), and carbon dioxide-assisted high-pressure processing (Boff et al. 2003) are some examples of technological processes that allow ascorbic acid retention and consequently prevent undesirable browning.

Lipid Browning

Protein-Oxidized Fatty Acid Reactions

The organoleptic and nutritional characteristics of several foods are affected by lipids, which can participate in chemical modifications during processing and storage. Lipid oxidation occurs in oils and lard, and also in foods with low amounts of lipids, such as products of vegetable origin. This reaction occurs in both unprocessed and processed foods, and although in some cases it is desirable, such as in the production of typical cheeses or fried-food aromas (Nawar 1985), in general, it can lead to undesirable odors and flavors (Nawar 1996). Quality properties such as appearance, texture, consistency, taste, flavor, and aroma can be adversely affected (Erikson 1987). Moreover, toxic compound formation and loss of nutritional quality can also be observed (Frankel 1980, Gardner 1989, Kubow 1990, 1992).

Although the lipids can be oxidized by both enzymatic and nonenzymatic reactions, the latter is the main involved reaction. This reaction arises from free radical or reactive oxygen species (ROS) generated during food processing and storage (Stadtman and Levine 2003), hydroperoxides being the initial products. As these compounds are quite unstable, a network of dendritic reactions, with different reaction pathways and a diversity of products, can take place (Gardner 1989). The enzymatic oxidation of lipids occurs sequentially. Lipolytic enzymes can act on lipids to produce polyunsaturated fatty acids that are then oxidized by either lipoxygenase or cyclooxygenase to form hydroperoxides or endoperoxides, respectively. Later, these compounds suffer a series of reactions to produce, among other compounds, long-chain fatty acids responsible for important characteristics and functions (Gardner 1995).

Via polymerization, brown-colored oxypolymers can be produced subsequently from the lipid oxidation derivatives (Khayat and Schwall 1983). However, interaction with nucleophiles such as the free amino group of amino acids, peptides, or proteins can also take place, because of the electrophilic character of free radicals produced during lipid oxidation, including hydroperoxides, peroxyl and alkoxyl radicals, carbonyl compounds and epoxides. As a result of this, end products different from those formed during oxidation of pure lipids can be also produced (Gillat and Rossell 1992, Schaich 2008). Both lipid oxidation

and oxidized lipid/amino acid reactions occur simultaneously (Hidalgo and Zamora 2002).

Radical transfer occurs early in lipid oxidation, and this process underlies the antioxidant effect for lipids. In addition, protein radicals can also transfer radicals to other proteins, lipids, carbohydrates, vitamins, and other molecules, especially in the presence of metal ions such as iron and copper (Schaich 2008). Reactions between proteins and free radicals and ROS suggest that proteins could protect lipids from oxidation if they are oxidized preferentially to unsaturated fatty acids (Elias et al. 2008). A study of continuous phase β-lactoglobulin in oil-in-water emulsion showed that tryptophan and cysteine side chains, but not methionine, oxidized before lipids (Elias et al. 2005).

The interaction between oxidized fatty acids and amino groups has been related to the browning detected during the progressive accumulation of lipofuscin (age-related yellow-brown pigments) in lysosomes of men and animals (Yin 1996). In foods, evidence of this reaction has been found during storage and processing of some fatty foods (Hidalgo et al. 1992, Nawar 1996), fermented alcoholic and nonalcoholic beverages (Herraiz 1996), in cocoa, chocolate (Herraiz 2000), salted sun-dried fish (Smith and Hole 1991), boiled and dried anchovy (Takiguchi 1992), cuttlefish (*Sepia pharaonis*) (Thanonkaew et al. 2007), meat and meat products (Mottram 1998, Herraiz and Papavergou 2004), smoked foodstuffs such as sausages, cheeses, and fish (Zotos et al. 2001, Herraiz et al. 2003, Papavergou and Herraiz 2003), and in rancid oils and fats with amino acids or proteins (Yamamoto and Kogure 1969, Okumura and Kawai 1970, Gillat and Rossell 1992, Guillen et al. 2005). For instance, interaction between different carbonyl compounds, mainly aldehydes, derived from lipid oxidation and lysine, tryptophan, methionine, and cysteine side chains of whey proteins has been shown to occur in dairy products such as raw and different heat-treated milks (pasteurized, UHT, and sterilized), as well as in infant formula (Nielsen et al. 1985, Meltretter et al. 2007, 2008, Meltretter and Pischetsrieder 2008).

Several studies have been carried out in model systems with the aim to investigate the role of lipids in nonenzymatic browning. The role of lipids in these reactions seems to be similar to that of the role of carbohydrates during the Maillard reaction (Hidalgo and Zamora 2000). Similar to the Maillard reaction, oxidized lipid/protein interactions comprise a huge number of several related reactions. The isolation and characterization of the involved products is very difficult, mainly in the case of intermediate products, which are unstable and are present in very low concentrations.

According to the mechanism proposed for the protein browning caused by acetaldehyde, the carbonyl compounds derived from unsaturated lipids readily react with protein-free amino groups, following the scheme of Figure 4.11, to produce, by repeated aldol condensations, the formation of brown pigments (Montgomery and Day 1965, Gardner 1979, Belitz and Grosch 1997).

More recently, another mechanism based on the polymerization of the intermediate products 2-(1-hydroxyalkyl) pyrroles has been proposed (Zamora and Hidalgo 1994, 1995). These authors, studying different model systems, tried to explain, at least

Figure 4.11. Formation of brown pigments by aldolic condensation (Hidalgo and Zamora 2000).

partially, the nonenzymatic browning and fluorescence produced when proteins are present during the oxidation of lipids (Figure 4.12). 2-(1-Hydroxyalkyl) pyrroles (I) have been found to be originated from the reaction of 4,5-epoxy-2-alkenals (formed during lipid peroxidation) with the amino group of amino acids and/or proteins, and their formation is always accompanied by the production of N-substituted pyrroles (II). Compounds derived from reaction of 4,5-epoxy-2-alkenals and phenylalanine have been found to be flavor compounds analogous to those of the Maillard reaction. Therefore, flavors traditionally connected to the Maillard reaction may also be produced as a result of lipid oxidation (Hidalgo and Zamora 2004, Zamora et al. 2006). N-substituted pyrroles are relatively stable and have been found in 22 fresh food products (cod, cuttlefish, salmon, sardine, trout, beef, chicken, pork, broad bean, broccoli, chickpea, garlic, green pea, lentil, mushroom, soybean, spinach, sunflower, almond, hazelnut, peanut, and walnut; Zamora et al. 1999). However, the N-substituted 2-(1-hydroxyalkyl) pyrroles are unstable and polymerize rapidly and spontaneously to produce brown macromolecules with fluorescent melanoidin-like characteristics (Hidalgo and Zamora 1993). Zamora et al. (2000) observed that the formation of pyrroles is a step immediately prior to the formation of color and fluorescence. Pyrrole formation and perhaps some polymerization finished before maximum color and fluorescence was achieved.

Although melanoidins starting from either carbohydrates or oxidized lipids would have analogous chemical structures, carbohydrate–protein and oxidized lipid–protein reactions are produced under different conditions. Hidalgo et al. (1999) studied the effect of pH and temperature in two model systems: (i) ribose and bovine serum albumin and (ii) methyl linoleate oxidation products and bovine serum albumin; they observed that from 25°C to 50°C, the latter exhibited higher browning than the former. Conversely, the browning produced in carbohydrate
Figure 4.12. Mechanism for nonenzymatic browning produced as a consequence of 2-(1-hydroxyalkyl)pyrrole polymerization (Hidalgo et al. 2003).

model system was increased at temperatures in the range of 80–120°C. The effect of pH on browning was similar in both oxidized lipid–protein and carbohydrate–protein model systems.

Some of the oxidized lipid–amino acid reaction products have been shown to have antioxidant properties when they are added to vegetable oils (Zamora and Hidalgo 1993, Alaiz et al. 1995, Alaiz et al. 1996). All of the pyrrole derivatives, with different substituents in the pyrrole ring, play an important role in the antioxidant activity of foods, being the sum of the antioxidant activities of the different compounds present in the sample (Hidalgo et al. 2003). Moreover, others studies have suggested that tetrahydro-β-carbolines derived from oxidation of tryptophan might act as antioxidants when they are absorbed and accumulated in the body, contributing to the antioxidant effect of fruit products naturally containing these compounds (Herraiz and Galisteo 2003). Likewise, Hidalgo et al. (2006a), in a study carried out with amino phospholipids (phosphatidylethanolamine (PE) and phosphatidylcholine (PC)), lysine (Lys), and mixtures of them in edible oils, demonstrated the *in situ* formation of oxidized lipid–amino compound reaction products (PE–Lys and PC–Lys) with antioxidative activities. More recently, studies have shown that antioxidative activity of such carbonyl-amine

products may be greatly increased with the addition of tocopherols and phytosterols such as β-sitosterol (Hidalgo et al. 2007, Hidalgo et al. 2009). Alaiz et al. (1997), in a study on the comparative antioxidant activity of both Maillard reaction compounds and oxidized lipid–amino acid reaction products, observed that both reactions seem to contribute analogously to increase the stability of foods during processing and storage.

Zamora and Hidalgo (2003a) studied the role of the type of fatty acid (methyl linoleate and methyl linolenate) and the protein (bovine serum albumin)–lipid ratio on the relative progression of the process involved when lipid oxidation occurs in the presence of proteins. These authors found that methyl linoleate was only slightly more reactive than the methyl linolenate for bovine serum albumin, producing an increase of protein pyrroles in the protein and an increase in the development of browning and fluorescence. In relation to the influence of the protein–lipid ratio on the advance of the reaction, the results observed in this study pointed out that a lower protein–lipid ratio increases sample oxidation and protein damage as a consequence of the antioxidant activity of the proteins. These authors also concluded that the changes produced in the color of protein–lipid samples were mainly due to oxidized lipid–protein reactions and not as consequence of polymerization of lipid oxidation products.

Analogous to the Maillard reaction, oxidized lipid and protein interaction can cause a loss of nutritional quality due to the destruction of essential amino acids, such as tryptophan, lysine, and methionine, and essential fatty acids. Moreover, a decrease in digestibility and inhibition of proteolytic and glycolytic enzymes can also be observed. In a model system of 4,5(E)-epoxy-2(E)-heptenal and bovine serum albumin, Zamora and Hidalgo (2001) observed denaturation and polymerization of the protein, and the proteolysis of this protein was impaired as compared with the intact protein. These authors suggested that the inhibition of proteolysis observed in oxidized lipid-damaged proteins may be related to the formation and accumulation of pyrrolized amino acid residues.

To date, although most of the studies have been conducted using model systems, the results obtained confirm that there is an interaction between lipid oxidation and the Maillard reaction. In fact, both reactions are so interrelated that they should be considered simultaneously to understand their consequences on foods when lipids, carbohydrates, and amino acids or proteins are present and should be included in one general pathway that can be initiated by both lipids and carbohydrates (Zamora et al. 2005a, 2005b). The complexity of the reaction is attributable to several fatty acids that can give rise to a number of lipid oxidation products that are able to interact with free amino groups. As summary, Figure 4.13 shows an example of a general pathway of pyrrole formation during polyunsaturated fatty acid oxidation in the presence of amino compounds.

Nonenzymatic Browning of Aminophospholipids

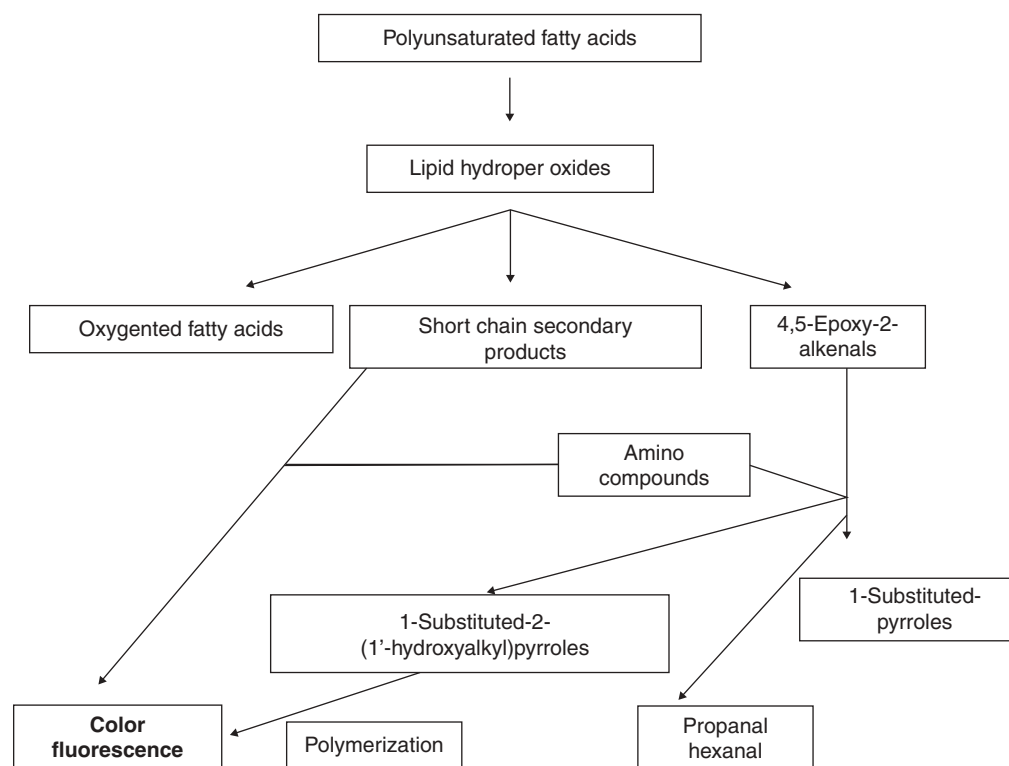
In addition to the above-mentioned studies on the participation of lipids in the browning reactions, several reports have been addressed on the amine-containing phospholipid interactions with carbohydrates. Because of the role of these membranous


Figure 4.13. General pathways of pyrrole formation during polyunsaturated fatty acids oxidation (Zamora and Hidalgo 1995).

functional lipids in the maintenance of cellular integrity, most of the studies have been conducted in biological samples (Bucala et al. 1993, Requena et al. 1997, Lertsiri et al. 1998, Oak et al. 2000, Oak et al. 2002). The glycation of membrane lipids can cause inactivation of receptors and enzymes, cross-linking of membrane lipids and proteins, membrane lipid peroxidation, and consequently, cell death. Amadori compounds derived from the interaction between aminophospholipids and reducing carbohydrates are believed to be key compounds for generating oxidative stress, causing several diseases.

In foods, this reaction can be responsible for deterioration during processing. Although nonenzymatic browning of aminophospholipids was detected for the first time in dried egg by Lea (1957), defined structures from such reaction were reported later by Utzmann and Lederer (2000). These authors demonstrated the interaction of PE with glucose in model systems; moreover, they found the corresponding Amadori compound in spray-dried egg yolk powders and lecithin products derived therefrom and proposed the Amadori compound content as a possible quality criterion. Oak et al. (2002) detected the Amadori compounds derived from glucose and lactose in several processed foods with high amounts of carbohydrates and lipids, such as infant formula, chocolate, mayonnaise, milk, and soybean milk; of these, infant formula contained the highest levels of Amadori-PEs. However, these compounds were not detected

in other foods due to differences in composition and relatively low temperatures used during the processing.

As an example, Figure 4.14 shows a scheme for the formation of the Amadori compounds derived from glucose and lactose with PE. Carbohydrates react with the amino group of PE to form an unstable Schiff's base, which undergoes an Amadori rearrangement to yield the stable PE-linked Amadori product (Amadori-PE).

On the other hand, similar to proteins, phospholipids, such as PE and ethanolamine, can react with secondary products of lipid peroxidation, such as 4,5-epoxyalkenals. Zamora and Hidalgo (2003b) studied this reaction in model systems, and they characterized different polymers responsible for brown color and fluorescence development, confirming that lipid oxidation products are able to react with aminophospholipids in a manner analogous to their reactions with protein amino groups; therefore, both amino phospholipids and proteins might compete for lipid oxidation products. Subsequent studies, besides to corroborate these findings (Zamora et al. 2004, Hidalgo et al. 2006b), showed the capacity of amino phospholipids to remove the cito- and genotoxic aldehydes produced in foods during lipid oxidation when its fatty acid chains were oxidized in the presence of an oxidative stress inducer. These results suggested that, in the presence of amino phospholipids, the oxidation of polyunsaturated fatty acid chains is not likely to produce toxic aldehydes in
Figure 4.14. Scheme for the glycation with glucose and lactose of phosphatidylethanolamine (PE) (Oak et al. 2002).

enough concentration to pose a significant risk for human health (Hidalgo et al. 2008).

Water Chemistry and Biochemistry

C. Chieh

INTRODUCTION

Water, the compound H_2O, is the most common food ingredient. Its rarely used chemical names are hydrogen oxide or dihydrogen monoxide. So much of this compound exists on the planet earth that it is often taken for granted. Water is present in solid, liquid, and gas forms in the small range of temperatures and pressures near the surface of the earth. Moreover, natural waters always have substances dissolved in them, and only elaborate processes produce pure water.

The chemistry and physics of water are organized studies of water: its chemical composition, formation, molecular structure, rotation, vibration, electronic energies, density, heat capacity, temperature dependency of vapor pressure, and its collective behavior in condensed phases (liquid and solid). In a broader sense, the study of water also includes interactions of water with atoms, ions, molecules, and biological matter. The knowledge of water forms the foundation for biochemistry and food chemistry. Nearly every aspect of biochemistry and food chemistry has something to do with water, because water is intimately linked to life, including the origin of life.

Science has developed many scientific concepts as powerful tools for the study of water. Although the study of water reveals a wealth of scientific concepts, only a selection of topics about water will be covered in the limited space here.

Biochemistry studies the chemistry of life at the atomic and molecular levels. Living organisms consist of many molecules. Even simple bacteria consist of many kinds of molecules. The interactions of the assembled molecules manifest life phenomena such as the capacity to extract energy or food, respond to stimuli, grow, and reproduce. The interactions follow

chemical principles, and water chemistry is a key for the beginning of primitive life forms billions of years ago. The properties of water molecules give us clues regarding their interactions with other atoms, ions, and molecules. Furthermore, water vapor in the atmosphere increases the average temperature of the atmosphere by 30 K (Wayne 2000), making the earth habitable. Water remains important for human existence, for food production, preservation, processing, and digestion.

Water is usually treated before it is used by food industries. After usage, wastewaters must be treated before it is discharged into the ecological system. After we ingest foods, water helps us to digest, dissolve, carry, absorb, and transport nutrients to their proper sites. It further helps hydrolyze, oxidize, and utilize the nutrients to provide energy for various cells, and eventually, it carries the biological waste and heat out of our bodies. Oxidations of various foods also produce water. How and why water performs these functions depend very much on its molecular properties.

THE COMPOUND WATER

A *compound* is a substance that is made up of two or more basic components called *chemical elements* (e.g., hydrogen, carbon, nitrogen, oxygen, iron) commonly found in food. *Water* is one of the tens of millions of compounds in and on earth.

The chemical equation and thermal dynamic data for the formation of water from hydrogen and oxygen gas is

$$2H_2(g) + O_2(g) + 2H_2O(l), \quad \Delta H^0 = -571.78 \text{ kJ}$$
The equation indicates that 2 mol of gaseous hydrogen, $H_2(g)$, react with 1 mol of gaseous oxygen, $O_2(g)$, to form 2 mol of liquid water. If all reactants and products are at their *standard states* of 298.15 K and 101.325 kPa (1.0 atm), formation of 2 mol of water releases 571.78 kJ of energy, as indicated by the negative sign for ΔH^0. Put in another way, the **heat of formation** of water, ΔH_f^0, is −285.89 (= −571.78/2) kJ/mol. Due to the large amount of energy released, the water vapor formed in the reaction is usually at a very high temperature compared with its standard state, liquid at 298.15 K. The heat of formation includes the heat that has to be removed when the vapor is condensed to liquid and then cooled to 298.15 K.

The reverse reaction, that is, the decomposition of water, is endothermic, and energy, a minimum of 285.89 kJ per mole of water, must be supplied. More energy is required by electrolysis to decompose water because some energy will be wasted as heat.

A hydrogen-containing compound, when fully oxidized, also produces water and energy. For example, the oxidation of solid (s) sucrose, $C_{12}H_{22}O_{11}$, can be written as

$$C_{12}H_{22}O_{11}(s) + 12O_2(g) = 12CO_2(g) + 11H_2O(l),$$
$$\Delta H^0 = -5640 \text{ kJ}$$
The amount of energy released, −5640 kJ, is called the *standard enthalpy of combustion* of sucrose. The chemical energy derived this way can also be used to produce high-energy biomolecules. When oxidation is carried out in human or animal bodies, the oxidation takes place at almost constant and low temperatures.

Of course, the oxidation of sucrose takes place in many steps to convert each carbon to CO_2.

THE POLAR WATER MOLECULES

During the twentieth century, the study of live organisms evolved from physiology and anatomy to biochemistry and then down to the molecular level of intermolecular relations and functions. Atoms and molecules are the natural building blocks of matter, including that of living organisms. Molecular shapes, structures, and properties are valuable in genetics, biochemistry, food science, and molecular biology, all involving water. Thus, we have a strong desire to know the shape, size, construction, dimension, symmetry, and properties of water molecules, because they are the basis for the science of food and life.

The structure of water molecules has been indirectly studied using X-ray diffraction, spectroscopy, theoretical calculations, and other methods. Specific molecular dimensions from these methods differ slightly, because they measure different properties of water under different circumstances. However, the O—H bond length of 95.72 pm (1 pm $= 10^{-12}$ m) and the H—O—H bond angle of 104.52° have been given after careful review of many recent studies (Petrenko and Whitworth 1999). The atomic radii of H and O are 120 pm and 150 pm, respectively. The bond length is considerably shorter than the sum of the atomic radii. Sketches of the water molecule are shown in Figure 5.1 (spherical atoms assumed).

Bonding among the elements H, C, N, and O is the key for biochemistry and life. Each carbon atom has the ability to form four chemical bonds. Carbon atoms can bond to other carbon atoms as well as to N and O atoms, forming chains, branched chains, rings, and complicated molecules. These carbon-containing compounds are called *organic compounds*, and they include foodstuff. The elements N and O have one and two more electrons, respectively, than carbon, and they have the capacity to form only three and two chemical bonds with other atoms. *Quantum mechanics* is a theory that explains the structure, energy, and properties of small systems such as atoms and molecules.

**Figure 5.1.** Some imaginative models of the water molecule, H_2O.

Figure 5.2. Molecules of CH_4, NH_3, and H_2O.

It provides excellent explanations for the electrons in the atom as well as the bonding of molecules, making the observed hard facts appear trivial (Bockhoff 1969).

The well-known inert elements helium (He) and neon (Ne) form no chemical bonds. The elements C, N, and O have four, five, and six electrons more than He, and these are called *valence electrons* (VE). Quantum mechanical designation for the VE of C, N, and O are $2s^2 2p^2$, $2s^2 2p^3$, and $2s^2 2p^4$, respectively. The C, N, and O atoms share electrons with four, three, and two hydrogen atoms, respectively. The formation of methane (CH_4), ammonia (NH_3), and water (H_2O) gave the C, N, and O atoms in these molecules eight VE. These molecules are related to each other in terms of bonding (Fig. 5.2).

The compounds CH_4, NH_3, and H_2O have zero, one, and two *lone pairs* (electrons not shared with hydrogen), respectively. Shared electron pairs form single bonds. The shared and lone pairs dispose themselves in space around the central atom symmetrically or slightly distorted when they have both bonding and lone pairs.

The lone pairs are also the negative sites of the molecule, whereas the bonded H atoms are the positive sites. The discovery of protons and electrons led to the idea of charge distribution in molecules. Physicists and chemists call NH_3 and H_2O *polar molecules* because their centers of positive and negative charge do not coincide. The polarizations in nitrogen and oxygen compounds contribute to their important roles in biochemistry and food chemistry. Elements C, N, and O play important and complementary roles in the formation of life.

Electronegativity is the ability of an atom to attract bonding electrons toward itself, and electronegativity increases in the order of H, C, N, and O (Pauling 1960). Chemical bonds between two atoms with different electronegativity are polar because electrons are drawn toward the more electronegative atoms. Thus, the polarity of the bonds increases in the order of H—C, H—N, and H—O, with the H atoms as the positive ends. The directions of the bonds must also be taken into account when the polarity of a whole molecule is considered. For example, the four slightly polar H—C bonds point toward the corner of a regular tetrahedron, and the polarities of the bonds cancel one

another. The symmetric CH_4 molecules do not have a net dipole moment, and CH_4 is nonpolar. However, the asymmetric NH_3 and H_2O molecules are polar. Furthermore, the lone electron pairs make the NH_3 and H_2O molecules even more polar. The lone pairs also make the H—N—H, and H—O—H angles smaller than the 109.5° of methane. The chemical bonds become progressively shorter from CH_4 to H_2O as well. These distortions cause the dipole moments of NH_3 and H_2O to be 4.903×10^{-30} Cm ($= 1.470$ D) and 6.187×10^{-30} Cm ($= 1.855$ D), respectively. The tendency for water molecules to attract the positive sites of other molecules is higher than that of the NH_3 molecule, because water is the most polar of the two.

Bond lengths and angles are based on their equilibrium positions, and their values change as water molecules undergo vibration and rotation or when they interact with each other or with molecules of other compounds. Thus, the bond lengths, bond angles, and dipole moments change slightly from the values given above. Temperature, pressure, and the presence of electric and magnetic fields also affect these values.

Using atomic orbitals, valence bond theory, and molecular orbital theory, quantum mechanics has given beautiful explanations regarding the shapes, distortions, and properties of these molecules. Philosophers and theoreticians have devoted their lives to providing a comprehensive and artistic view of the water molecules.

WATER VAPOR CHEMISTRY AND SPECTROSCOPY

Spectroscopy is the study of the absorption, emission, or interaction of electromagnetic radiation by molecules in solid, liquid, and gaseous phases. The spectroscopic studies of vapor, in which the H_2O molecules are far apart from each other, reveal a wealth of information about individual H_2O molecules.

Electromagnetic radiation (light) is the transmission of energy through space via no medium by the oscillation of mutually perpendicular electric and magnetic fields. The oscillating *electromagnetic waves* move in a direction perpendicular to both fields at the speed of light ($c = 2.997925 \times 10^8$ m/s). Max Planck

(1858–1947) thought the waves also have particle-like properties except that they have no mass. He further called the light particles *photons,* meaning bundles of light energy. He assumed the *photon's energy, E,* to be proportional to its frequency. The proportional constant h (= 6.62618×10^{-34} J/s), now called the *Planck constant* in his honor, is universal. The validity of this assumption was shown by Albert Einstein's photoelectric-effect experiment.

Max Planck theorized that a bundle of energy converts into a light wave. His theory implies that small systems can be only at certain energy states called *energy levels*. Due to quantization, they can gain or lose only specific amounts of energy. Spectroscopy is based on these theories. Water molecules have quantized energy levels for their rotation, vibration, and electronic transitions. Transitions between energy levels result in the emission or absorption of photons.

The electromagnetic spectrum has been divided into several regions. From low energy to high energy, these regions are long radio wave, short radio wave, microwave, infrared (IR), visible, ultraviolet (UV), X rays, and gamma rays. Visible light of various colors is actually a very narrow region within the spectrum. On the other hand, IR and UV regions are very large, and both are often further divided into near and far, or A and B, regions.

Microwaves in the electromagnetic spectrum range from 300 MHz (3×10^8 cycles/s) to 300 GHz (3×10^{11} cycles/s). The water molecules have many rotation modes. Their pure rotation energy levels are very close together, and the transitions between pure rotation levels correspond to microwave photons. *Microwave spectroscopy* studies led to, among other valuable information, precise bond lengths and angles.

Water molecules vibrate, and there are some fundamental vibration modes. The three fundamental vibration modes of water are symmetric stretching (for $^1H_2{}^{16}O$), ν_1, 3657 cm^{-1}, bending ν_2, 1595 cm^{-1}, and asymmetric stretching ν_3, 3756 cm^{-1}. These modes are illustrated in Figure 5.3. Vibration energy levels are represented by three integers, ν_1, ν_2, and ν_3, to represent the combination of the basic modes. The frequencies of fundamental vibration states differ in molecules of other isotopic species (Lemus 2004).

Water molecules absorb photons in the IR region, exciting them to the fundamental and combined overtones. As pointed out earlier, water molecules also rotate. The rotation modes combine with any and all vibration modes. Thus, transitions corresponding to the vibration-rotation energy levels are very complicated, and they occur in the *infrared* (frequency range 3×10^{11}–4×10^{14} Hz) region of the electromagnetic spectrum. High-resolution *IR spectrometry* is powerful for the study of water in the atmosphere and for water analyses (Bernath 2002a).

Visible light spans a narrow range, with wavelengths between 700 nm (red) and 400 nm (violet) (frequency 4.3–7.5 $\times 10^{14}$ Hz, wave number 14,000–25,000 cm^{-1}, photon energy 2–4 eV). It is interesting to note that the sun surface has a temperature of about 6000 K, and the visible region has the highest intensity of all wavelengths. The solar emission spectrum peaks at 630 nm (16,000 cm^{-1}, 4.8×10^{14} Hz), which is orange (Bernath 2002b).

Water molecules that have energy levels corresponding to very high overtone vibrations absorb photons of visible light, but the absorptions are very weak. Thus, visible light passes through water vapor with little absorption, resulting in water being transparent. On the other hand, the absorption gets progressively weaker from red to blue (Carleer et al. 1999). Thus, large bodies of water appear slightly blue.

Because visible light is only very weakly absorbed by water vapor, more than 90% of light passes through the atmosphere and reaches the earth's surface. However, the water droplets in clouds (water aerosols) scatter, refract, and reflect visible light, giving rainbows and colorful sunrises and sunsets.

Like the IR region, the *ultraviolet* (UV, 7×10^{14}–1×10^{18} Hz) region spans a very large range in the electromagnetic spectrum. The photon energies are rather high, more than 4 eV, and they are able to excite the electronic energy states of water molecules in the gas phase.

There is no room to cover the molecular orbitals (Gray 1964) of water here, but by analogy to electrons in atomic orbitals one can easily imagine that molecules have molecular orbitals or energy states. Thus, electrons can also be promoted to higher empty molecular orbitals after absorption of light energy. Ultraviolet photons have sufficiently high energies to excite electrons into higher molecular orbitals. Combined with vibrations and rotations, these transitions give rise to very broad bands in the UV spectrum. As a result, gaseous, liquid, and solid forms of water strongly absorb UV light (Berkowitz 1979). The

Figure 5.3. The three principal vibration modes of the water molecule, H_2O: ν_1, symmetric stretching; ν_2, bending; and ν_3, asymmetric stretching.

absorption intensities and regions of water vapor are different from those of ozone, but both are responsible for UV absorption in the atmosphere. Incidentally, both triatomic water and ozone molecules are bent.

HYDROGEN BONDING AND POLYMERIC WATER IN VAPOR

Attraction between the lone pairs and hydrogen among water molecules is much stronger than any dipole–dipole interactions. This type of attraction is known as the hydrogen bond (O—H—O), a very prominent feature of water. Hydrogen bonds are directional and are more like covalent bonds than strong dipole–dipole interactions. Each water molecule has the capacity to form four hydrogen bonds, two by donating its own H atoms and two by accepting H atoms from other molecules. In the structure of ice, to be described later, all water molecules, except those on the surface, have four hydrogen bonds.

Attractions and strong hydrogen bonds among molecules form *water dimers* and polymeric *water clusters* in water vapor. Microwave spectroscopy has revealed their existence in the atmosphere (Goldman et al. 2001, Huisken et al. 1996).

As water dimers collide with other water molecules, trimer and higher polymers form. The directional nature of the hydrogen bond led to the belief that water clusters are linear, ring, or cage-like rather than aggregates of molecules in clusters (see Fig. 5.4). Water dimers, chains, and rings have one and two hydrogen-bonded neighbors. There are three neighbors per molecule in cage-like polymers. Because molecules are free to move in the gas and liquid state, the number of nearest neigh-

bors is between four and six. Thus, water dimers and clusters are entities between water vapor and condensed water (Bjorneholm et al. 1999).

By analogy, when a few water molecules are intimately associated with biomolecules and food molecules, their properties would be similar to those of clusters.

CONDENSED WATER PHASES

Below the critical temperature of 647 K (374°C) and under the proper pressure, water molecules condense to form a liquid or solid—*condensed water*. Properties of water, ice, and vapor must be considered in freezing, pressure-cooking, and microwave heating. In food processing, these phases transform among one another. The transitions and the properties of condensed phases are manifestations of microscopic properties of water molecules. However, condensation modifies microscopic properties such as bond lengths, bond angles, vibration, rotation, and electronic energy levels. The same is true when water molecules interact with biomolecules and food molecules. All phases of water play important parts in biochemistry and food science.

Water has many anomalous properties, which are related to polarity and hydrogen bonding. The melting point (mp), boiling point (bp), and critical temperature are abnormally high for water. As a rule, the melting and boiling points of a substance are related to its molecular mass; the higher the molar mass, the higher the mp and bp. Mp and bp of water (molar mass 18, mp 273 K, bp 373 K) are higher than those of hydrogen compounds of adjacent elements of the same period, NH_3 (molar mass 17,

Figure 5.4. Hydrogen bonding in water dimers and cyclic forms of trimer and tetramer. Linear and transitional forms are also possible for trimers, tetramers, and polymers.

Table 5.1. Properties of Liquid Water at 298 K

Heat of formation ΔH_f	285.89 kJ mol^{-1}
Density at 3.98°C	1.000 g cm^3
Density at 25°C	0.9970480 g cm^3
Heat capacity	4.17856 J g^{-1}K^{-1}
$\Delta H_{vaporization}$	55.71 kJ mol^{-1}
Dielectric constant	80
Dipole moment	6.24×10^{-30} C m
Viscosity	0.8949 mPa s
Velocity of sound	1496.3 m s
Volumetric thermal expansion coefficient	0.0035 cm^3 g^{-1}K^{-1}

mp 195 K, bp 240 K) and HF (molar mass 20, mp 190 K, bp 293 K). If we compare the hydrogen compounds of elements from the same group (O, S, Se, and Te), the normal bp of H_2O (373 K) is by far the highest among H_2S, H_2Se, and H_2Te. Much energy (21 kJ mol^{-1}) is required to break the hydrogen bonds. The strong hydrogen bonds among water molecules in condensed phase result in anomalous properties, including the high enthalpies (energies) of fusion, sublimation, and evaporation given in Table 5.1. Internal energies and entropies are also high.

Densities of water and ice are also anomalous. Ice at 273 K is 9% less dense than water, but solids of most substances are denser than their liquids. Thus, ice floats on water, extending 9% of its volume above water. Water is the densest at 277 K (4°C). Being less dense at the freezing point, still water freezes from the top down, leaving a livable environment for aquatic organisms. The hydrogen bonding and polarity also lead to aberrant high surface tension, dielectric constant, and viscosity.

We illustrate the phase transitions between ice, liquid (water), and vapor in a phase diagram, which actually shows the equilibria among the common phases. Experiments under high pressure observed at least 13 different ices, a few types of amorphous solid water, and even the suggestion of two forms of liquid water (Klug 2002, Petrenko and Whitworth 1999). If these phases were included, the phase diagram for water would be very complicated.

Solid H_2O

At 273.16 K, ice, liquid H_2O, and H_2O vapor at 611.15 Pa coexist and are at equilibrium; the temperature and pressure define the *triple-point* of water. At the normal pressure of 101.3 kPa (1 atm), ice melts at 273.15 K. The temperature for the equilibrium water vapor pressure of 101.3 kPa is the bp, 373.15 K.

Under ambient pressure, ice often does not begin to form until it is colder than 273.15 K, and this is known as *supercooling*, especially for ultrapure water. The degree of supercooling depends on volume, purity, disturbances, the presence of dust, the smoothness of the container surface, and similar factors. Crystallization starts by *nucleation*, that is, formation of ice-structure clusters sufficiently large that they begin to grow and become crystals. Once ice begins to form, the temperature will return to the freezing point. At 234 K (-39°C), tiny drops of ultrapure water would suddenly freeze, and this is known as *homogeneous nucleation* (Franks et al. 1987). Dust particles and roughness of the surface promote nucleation and help reduce supercooling for ice and frost formation.

At ambient conditions, *hexagonal ice* (**Ih**) is formed. Snowflakes exhibit the hexagonal symmetry. Their crystal structure is well known (Kamb 1972). Every oxygen atom has four hydrogen bonds around it, two formed by donating its two H atoms, and two by accepting the H atoms of neighboring molecules. The hydrogen bonds connecting O atoms are shown in Figure 5.5. In normal ice, Ih, the positions of the H atoms are random or disordered. The hydrogen bonds O—H—O may be slightly bent, leaving the H—O—H angle closer to 105° than to 109.5°, the ideal angle for a perfect tetrahedral arrangement. Bending the hydrogen bond requires less energy than opening the H—O—H angle. Bending of the hydrogen bond and the exchange of H atoms among molecules, forming H_3O^+ and OH^- in the solids,

(Ih)   (Ic)

Figure 5.5. The crystal structures of ice hexagonalice (**Ih**) and cubic ice (**Ic**). Oxygen atoms are placed in two rings in each to point out their subtle difference. Each line represents a hydrogen bond O—H—O, and the H atoms are randomly distributed such that on average, every oxygen atom has two O—H bonds of 100 pm. The O—H—O distance is 275 pm. The idealized tetrahedral bond angles around oxygen are 1095°.

give rise to the disorder of the H atoms. These rapid exchanges are in a dynamic equilibrium.

In the structure of Ih, six O atoms form a ring; some of them have a chair form, and some have a boat form. Two configurations of the rings are marked by spheres representing the O atoms in Figure 5.5. Formation of the hydrogen bond in ice lengthens the O—H bond distance slightly from that in a single isolated water molecule. All O atoms in Ih are completely hydrogen bonded, except for the molecules at the surface. Maximizing the number of hydrogen bonds is fundamental to the formation of solid water phases. Pauling (1960) pointed out that formation of hydrogen bonds is partly an electrostatic attraction. Thus, the bending of O—H—O is expected. Neutron diffraction studies indicated bent hydrogen bonds.

Since only four hydrogen bonds are around each O atom, the structure of Ih has rather large channels at the atomic scale. Under pressure, many other types of structures are formed. In liquid water, the many tetrahedral hydrogen bonds are formed with immediate neighbors. Since water molecules constantly exchange hydrogen-bonding partners, the average number of nearest neighbors is usually more than four. Therefore, water is denser than Ih.

Other Phases of Ice

Under high pressures, water forms many fascinating H_2O solids. They are designated by Roman numerals (e.g., ice XII; Klug 2002, Petrenko and Whitworth 1999). Some of these solids were known as early as 1900. Phase transitions were studied at certain temperatures and pressures, but metastable phases were also observed.

At 72 K, the disordered H atoms in Ih transform into an ordered solid called ice XI. The oxygen atoms of Ih and ice XI arrange in the same way, and both ices have a similar density, 0.917 Mg m^{-3}.

Under high pressure, various denser ices are formed. Ice II was prepared at a pressure about 1 GPa (1 GPa = 10^9 Pa) in 1900, and others with densities ranging from 1.17 to 2.79 Mg m^{-3} have been prepared during the twentieth century. These denser ices consist of hydrogen bond frameworks different from Ih and XI, but each O atom is hydrogen-bonded to four other O atoms.

Cubic ice, Ic, has been produced by cooling vapor or droplets below 200 K (Mayer and Hallbrucker 1987, Kohl et al. 2000). More studies showed the formation of Ic between 130 K and 150 K. Amorphous (glassy) water is formed below 130 K, but above 150 K Ih is formed. The hydrogen bonding and intermolecular relationships in Ih and Ic are the same, but the packing of layers and symmetry differ (see Fig. 5.5). The arrangement of O atoms in Ic is the same as that of the C atoms in the diamond structure. Properties of Ih and Ic are very similar. Crystals of Ic have cubic or octahedral shapes, resembling those of salt or diamond. The conditions for their formation suggest their existence in the upper atmosphere and in the Antarctic.

As in all phase transitions, energy drives the transformation between Ih and Ic. Several forms of amorphous ice having various densities have been observed under different temperatures and pressures. Unlike crystals, in which molecules are packed in an orderly manner, following the symmetry and periodic rules of the crystal system, the molecules in *amorphous ice* are immobilized from their positions in liquid. Thus, amorphous ice is often called frozen water or glassy water.

When small amounts of water freeze suddenly, it forms amorphous ice or glass. Under various temperatures and pressures, it can transform into high-density (1.17 mg/m^3) amorphous water, and very high-density amorphous water. Amorphous water also transforms into various forms of ice (Johari and Anderson 2004). The transformations are accompanied by energies of transition. A complicated phase diagram for ice transitions can be found in *Physics of Ice* (Petrenko and Whitworth 1999).

High pressures and low temperatures are required for the existence of other forms of ice, and currently these conditions are seldom involved in food processing or biochemistry. However, their existence is significant for the nature of water. For example, their structures illustrate the deformation of the ideal tetrahedral arrangement of hydrogen bonding presented in Ih and Ic. This feature implies flexibility when water molecules interact with foodstuffs and with biomolecules.

Vapor Pressure of Ice Ih

The equilibrium vapor pressure is a measure of the ability or potential of the water molecules to escape from the condensed phases to form a gas. This potential increases as the temperature increases. Thus, vapor pressures of ice, water, and solutions are important quantities. The ratio of equilibrium vapor pressures of foods divided by those of pure water is called the *water activity*, which is an important parameter for food drying, preservation, and storage.

Ice sublimes at any temperature until the system reaches equilibrium. When the vapor pressure is high, molecules deposit on the ice to reach equilibrium. Solid ice and water vapor form an equilibrium in a closed system. The amount of ice in this equilibrium and the free volume enclosing the ice are irrelevant, but the water vapor pressure or partial pressure matters. The equilibrium pressure is a function of temperature, and detailed data can be found in handbooks, for example, the *CRC Handbook of Chemistry and Physics* (Lide 2003). This handbook has a new edition every year. More recent values between 193 K and 273 K can also be found in *Physics of Ice* (Petrenko and Whitworth 1999).

The equilibrium vapor pressure of ice Ih plotted against temperature *(T)* is shown in Figure 5.6. The line indicates equilibrium conditions, and it separates the pressure–temperature *(P–T)* graph into two domains: vapor tends to deposit on ice in one, and ice sublimes in the other. This is the ice Ih—vapor portion of the phase diagram of water.

Plot of ln *P* versus 1/*T* shows a straight line, and this agrees well with the Clausius-Clapeyron equation. The negative slope gives the enthalpy of the phase transition, ΔH, divided by the gas constant R (= 8.3145 J/K/mol).
$$\frac{(d(\ln P))}{(d(1/T))} = \frac{-\Delta H}{R}$$

Figure 5.6. Equilibrium vapor pressure (Pa) of ice as a function of temperature (K).

Figure 5.7. Variation of viscosity (1.793 mPa s), dielectric constant (87.90), surface tension (75.64 mN/m), heat capacity Cp (4.2176 J g^{-1}K^{-1}), and thermal conductivity (561.0 W K^{-1}m^{-1}) of water from their values at 273.16 K to 373.16 K (0 and 100°C). Values at 273.15°K are given.

This simplified equation gives an estimate of the vapor pressure (in Pa) of ice at temperatures in a narrow range around the triple point.

$$P = 611.15 \exp\left(-6148\left(\frac{1}{T} - \frac{1}{273.16}\right)\right)$$

The value 6148 is the enthalpy of sublimation ($\Delta_{sub}H = 51.1$ J/ mol, varies slightly with temperature) divided by the gas constant R. Incidentally, the enthalpy of sublimation is approximately the sum of the enthalpy of fusion (6.0 J/mol) for ice and the heat of vaporization (45.1 J/mol, varies with temperature) of water at 273 K.

LIQUID H$_2$O—WATER

We started the chapter by calling the compound H$_2$O water, but most of us consider *water* the liquid H$_2$O. In terms of food processing, the liquid is the most important state. Water is contained in food, and it is used for washing, cooking, transporting, dispersing, dissolving, combining, and separating components of foods. Food drying involves water removal, and fermentation uses water as a medium to convert raw materials into commodities. Various forms of water ingested help digest, absorb, and transport nutrients to various part of the body. Water further facilitates biochemical reactions to sustain life. The properties of water are the basis for its many applications.

Among the physical properties of water, the heat capacity (4.2176 J g^{-1}K^{-1} at 273.15 K) varies little between 273.15 and 373.15 K. However, this value decreases, reaches a minimum at about 308 K, and then rises to 4.2159–4.2176 J g^{-1}K^{-1} at 373.15 K (see Fig. 5.7).

The viscosity, surface tension, and dielectric constant of liquid H$_2$O decrease as temperature increases (see Fig. 5.7). These three properties are related to the extent of hydrogen bonding and the ordering of the dipoles. As thermal disorder increases with rising temperature, these properties decrease. To show the variation, the properties at other temperatures are divided by the same property at 273 K. The ratios are then plotted as a function of temperature. At 273.15 K (0°C), all the ratios are unity (1). The thermal conductivity, on the other hand, increases with temperature. Thus, the thermal conductivity at 373 K (679.1 W K^{-1}m^{-1}) is 1.21 times that at 273 K (561.0 W K^{-1}m^{-1}). Warm water better conducts heat. Faster moving molecules transport energy faster. The variations of these properties play important roles in food processing or preparation. For example, as we shall see later, the dielectric constant is a major factor for the microwave heating of food, and heat conductivity plays a role cooking food.

Densities of other substances are often determined relative to that of water. Therefore, density of water is a primary reference. Variation of density with temperature is well known, and accurate values are carefully measured and evaluated especially between 273 K and 313 K (0–40°C). Two factors affect water density. Thermal expansion reduces its density, but the reduced number of hydrogen bonds increases its density. The combined effects resulted in the highest density at approximately 277 K (4°C). Tanaka et al. (2001) has developed a formula to calculate the density within this temperature range, and the *CRC Handbook of Chemistry and Physics* (Lide 2003) has a table listing these values. The variation of water density between the freezing point and the bp is shown in Figure 5.8. The densities are 0.9998426, 0.9999750, and 0.9998509 Mg m^{-3} at 0, 4, and 8°C, respectively. The decrease in density is not linear, and at 100°C, the density is 0.95840 Mg m^{-3}, a decrease of 4% from its maximum.

Vapor Pressure of Liquid H$_2$O

Equilibrium vapor pressure of water (Fig. 5.9) increases with temperature, similar to that of ice. At the triple point, the vapor
Figure 5.8. Density of water mg m^{-3} as a function of temperature (°C).

pressures of ice Ih and water are the same, 0.611 kPa, and the boiling point (373.15 K, 100°C) is the temperature at which the vapor pressure is 101.325 kPa (1 atm). At slightly below 394 K (121°C), the vapor pressure is 202.65 kPa (2.00 atm). At 473 and 574 K, the vapor pressures are 1553.6 and 8583.8 kPa, respectively. The vapor pressure rises rapidly as temperature increases. The lowest pressure to liquefy vapor just below the critical temperature, 373.98°C, is 22,055 kPa (217.67 atm), and this is known as the critical pressure. Above 373.98°C, water cannot be liquefied, and the fluid is called supercritical water.

The partial pressure of H_2O in the air at any temperature is the **absolute humidity**. When the partial pressure of water vapor in the air is the equilibrium vapor pressure of water at the same temperature, the **relative humidity** is 100%, and the air is saturated with water vapor. The partial vapor pressure in the air divided by the equilibrium vapor pressure of water at the temperature of the air is the **relative humidity**, expressed as a percentage. The temperature at which the vapor pressure in the air becomes saturated is the **dew point**, at which dew begins to form. Of course, when the dew point is below 273 K or 0°C, ice crystals (frost) begin to form. Thus, the relative humidity can be measured by finding the dew point and then dividing the equilibrium vapor pressure at the dew point by the equilibrium vapor pressure of water at the temperature of the air. The transformations between solid, liquid, and gaseous water play important roles in hydrology and in transforming the earth's surface. Solar energy causes phase transitions of water that make the weather.

TRANSFORMATION OF SOLID, LIQUID, AND VAPOR

Food processing and biochemistry involve transformations among solid, liquid, and vapor of water. Therefore, it is important to understand ice–water, ice–vapor, and water–vapor transformations and their equilibria. These transformations affect our daily lives as well. A map or diagram is helpful in order to comprehend these natural phenomena. Such a map, representing or explaining these transformations, is called a *phase diagram* (see Fig. 5.10). A sketch must be used because the range of pressure involved is too large for the drawing to be on a linear scale.

The curves representing the equilibrium vapor pressures of ice and water as functions of temperature meet at the *triple point* (see Fig. 5.10). The other end of the vapor pressure curve is the critical point. The mps of ice Ih are 271.44, 273.15, and 273.16 K at 22,055 kPa (the critical pressure), 101.325 kPa, and 0.611 kPa (the triple point), respectively. At a pressure of 200,000 kPa, Ih melts at 253 K. Thus, the line linking all these points represents the mp of Ih at different pressures. This line divides the conditions (pressure and temperature) for the formation of solid and liquid. Thus, the phase diagram is roughly divided into regions of solid, liquid, and vapor.

Ice Ih transforms into the ordered ice XI at low temperature. In this region and under some circumstance, Ic is also formed. The transformation conditions are not represented in Figure 5.10, and neither are the transformation lines for other ices. These occur at much higher pressures in the order of gigapascals. A box at the top of the diagram indicates the existence of these phases, but the conditions for their transformation are not given. Ices II–X, formed under gigapascals pressure, were mentioned earlier. Ice VII forms at greater than 10 GPa and at a temperature higher than the boiling point of water.

Formation and existence of these phases illustrate the various hydrogen bonding patterns. They also show the many possibilities of H_2O-biomolecule interactions.

SUBCRITICAL AND SUPERCRITICAL WATERS

Water at temperatures between the boiling and critical points (100–373.98°C) is called subcritical water, whereas the phase

Figure 5.9. Equilibrium vapor pressure of water as a function of temperature.

Figure 5.10. A sketch outlining the phase diagram of ice, water, and vapor.

above the critical point is *supercritical water*. In the seventeenth century, Denis Papin (a physicist) generated high-pressure steam using a closed boiler, and thereafter pressure canners have been used to preserve food. Pressure cookers were popular during the twentieth century. Pressure cooking and canning use subcritical water. Plastic bags are gradually replacing cans, and food processing faces new challenges.

Properties of subcritical and supercritical water such as dielectric constant, polarity, surface tension, density, viscosity, and others, differ from those of normal water. These properties can be tuned by adjusting water temperature. At high temperature, water is an excellent solvent for nonpolar substances such as those for flavor and fragrance. Supercritical water has been used for wastewater treatment to remove organic matter, and this application will be interesting to the food industry if companies are required to treat their wastes before discharging them into the environment. The conditions for supercritical water cause polymers to depolymerize and nutrients to degrade. More research will tell whether supercritical water will convert polysaccharides and proteins into useful products.

Supercritical water is an oxidant, which is desirable for the destruction of substances. It destroys toxic material without the need of a smokestack. Water is a "green" solvent and reagent, because it causes minimum damage to the environment. Therefore, the potential for supercritical water is great.

AQUEOUS SOLUTIONS

Water dissolves a wide range of natural substances. Life began in natural waters, *aqueous solutions*, and continuation of life depends on them.

Water, a polar solvent, dissolves polar substances. Its polarity and its ability to hydrogen bond make it a nearly universal solvent. Water-soluble polar substances are *hydrophilic*, whereas nonpolar substances insoluble in water are *hydrophobic* or *lipophilic*. Substances whose molecules have both polar and nonpolar parts are *amphiphilic*. These substances include detergents, proteins, aliphatic acids, alkaloids, and some amino acids.

The high dielectric constant of water makes it an ideal solvent for ionic substances, because it reduces the attraction between positive and negative ions in *electrolytes*: acids, bases, and salts. Electrolyte solutions are intimately related to food and biological sciences.

COLLIGATIVE PROPERTIES OF AQUEOUS SOLUTIONS

Vapor pressure of an aqueous solution depends only on the concentration of the solute, not on the type and charge of the solute. Vapor pressure affects the mp, the bp, and the osmotic pressure, and these are *colligative properties*.

In a solution, the number of moles of a component divided by the total number of moles of all components is the *mole fraction* of that component. This is a useful parameter, and the mole fraction of any pure substance is unity. When 1 mol of sugar dissolves in 1.0 kg (55.56 mol) of water, the mole fraction of water is reduced to 0.9823, and the mole fraction of sugar is 0.0177. Raoult's law applies to aqueous solutions. According to it, the vapor pressure of a solution at temperature T is the product of mole fraction of the solvent and its vapor pressure at T. Thus, the vapor pressure of this solution at 373 K is 99.53 kPa (0.9823 atm). In general, the vapor pressure of a solution at the normal bp is lower than that of pure water, and a higher temperature is required for the vapor pressure to reach 101.3 kPa (1 atm). The net increase in the boiling temperature of a solution is known as the *boiling point elevation*.

Ice formed from a dilute solution does not contain the solute. Thus, the vapor pressure of ice at various temperatures does not change, but the vapor pressure of a solution is lower than that of ice at the freezing point. Further cooling is required for ice to form, and the net lowering of vapor pressure is the *freezing point depression*.

The freezing points and bps are temperatures at ice–water and water–vapor (at 101.3 kPa) equilibria, not necessarily the temperatures at which ice begins to form or boiling begins. Often, the temperature at which ice crystals start to form is lower than the mp, and this is known as *supercooling*. The degree of supercooling depends on many other parameters revealed by a systematic study of heterogeneous nucleation (Wilson et al. 2003). Similarly, the inability to form bubbles results in *superheating*. Overheated water boils explosively due to the sudden formation of many large bubbles. Supercooling and superheating are nonequilibrium phenomena, and they are different from freezing point depression and bp elevation.

The temperature differences between the freezing points and bps of solutions and those of pure water are proportional to the concentration of the solutions. The proportionality constants are *molar freezing point depression* ($K_f = -1.86$ K mol^{-1} kg) and the *molar boiling point elevation* ($K_b = 0.52$ K mol^{-1} kg), respectively. In other words, a solution containing one mole of nonvolatile molecules per kilogram of water freezes at $1.86°$ below 273.15 K, and boils $0.52°$ above 373.15 K. For a solution with concentration C, measured in moles of particles (molecules and positive and negative ions counted separately) per kilogram of water, the bp elevation or freezing point depression ΔT can be evaluated:

$$\Delta T = KC,$$

where K represents K_f or K_b for freezing point depression or bp elevation, respectively. This formula applies to both cases. Depending on the solute, some aqueous solutions may deviate from Raoult's law, and the above formulas give only estimates.

In freezing or boiling a solution of a nonvolatile solute, the solid and vapor contain only H_2O, leaving the solute in the solution. A solution containing volatile solutes will have a total vapor pressure due to all volatile components in the solution. Its bp is no longer that of water alone. Freezing point depression and bp elevation are both related to the vapor pressure. In general,

a solution of nonvolatile substance has a lower vapor pressure than that of pure water. The variations of these properties have many applications, some in food chemistry and biochemistry.

It is interesting to note that some fish and insects have antifreeze proteins that depress the freezing point of water to protect them from freezing in the arctic sea (Marshall et al. 2004).

Osmotic pressure is usually defined as the pressure that must be applied to the side of the solution to prevent the flow of the pure solvent passing a semipermeable membrane into the solution. Experimental results show that osmotic pressure is equal to the product of total concentration of molecules and ions (C), the gas constant (R = 8.3145 J/mol/K), and the temperature (T in K):

Osmotic pressure $= CRT$.

The expression for osmotic pressure is the same as that for ideal gas. Chemists calculate the pressure using a concentration based on mass of the solvent. Since solutions are never ideal, the formula gives only estimates. The unit of pressure works out if the units for C are in mol/m^3, since 1 J $= 1$ Pa m^3. Concentration based on mass of solvent differs only slightly from that based on volume of the solution.

An *isotonic solution* (*isosmotic*) is one that has the same osmotic pressure as another. Solutions with higher and lower osmotic pressures are called *hypertonic* (*hyperosmotic*), and *hypotonic* (*hypoosmotic*), respectively. Raw food animal and plant cells submerged in isotonic solutions with their cell fluids will not take up or lose water even if the cell membranes are semipermeable. However, in plant, soil, and food sciences, *water potential gradient* is the driving force or energy directing water movement. Water moves from high-potential sites to low-potential sites. Water moves from low osmotic pressure solutions to high osmotic pressure solutions. For consistency and to avoid confusion, negative osmotic pressure is defined as *osmotic potential*. This way, osmotic potential is a direct component of water potential for gradient consideration. For example, when red blood cells are placed in dilute solutions, their osmotic potential is negative. Water diffuses into the cells, resulting in the swelling or even bursting of the cells. On the other hand, when cells are placed in concentrated (hypertonic) saline solutions, the cells will shrink due to water loss.

Biological membranes are much more permeable than most man-made phospholipid membranes because they have specific membrane-bound proteins acting as water channels. Absorption of water and its transport throughout the body is more complicated than osmosis.

SOLUTION OF ELECTROLYTES

Solutions of acids, bases, and salts contain ions. Charged ions move when driven by an electric potential, and electrolyte solutions conduct electricity. These ion-containing substances are called *electrolytes*. As mentioned earlier, the high dielectric constant of water reduces the attraction of ions within ionic solids and dissolves them. Furthermore, the polar water molecules surround ions, forming *hydrated ions*. The concentration of all ions

and molecular substances in a solution contributes to the osmotic potential.

Water can also be an acid or a base, because H_2O molecules can receive or provide a proton (H^+). Such an exchange by water molecules in pure water, forming *hydrated protons* (H_3O^+ or $(H_2O)_4H^+$), is called *self-ionization*. However, the extent of ionization is small, and pure water is a very poor conductor.

Self-Ionization of Water

The self-ionization of water is a dynamic equilibrium,

$$H_2O(l) \leftrightarrow H^+(aq) + OH^-(aq),$$
$$K_w = [H^+][OH^-] = 10^{-14} \text{ at 298 K and 1 atm}$$

where $[H^+]$ and $[OH^-]$ represent the molar concentrations of H^+ (or H_3O^+) and OH^- ions, respectively, and K_w is called the *ion product of water*. Values of K_w under various conditions have been evaluated theoretically (Marshall and Franck 1981, Tawa and Pratt 1995). Solutions in which $[H^+] = [OH^-]$ are said to be *neutral*. Both pH and pOH, defined by the following equations, have a value of 7 at 298 K for a neutral solution

$$pH = -\log_{10}[H^+] = pOH = -\log_{10}[OH^-] = 7.\text{(at 298 K)}$$

The H^+ represents a hydrated proton (H_3O^+), which dynamically exchanges a proton with other water molecules. The self-ionization and equilibrium are present in water and all aqueous solutions.

Solutions of Acids and Bases

Strong acids perchloric acid ($HClO_4$), Chloric acid ($HClO_3$), hydrochoric acid (HCl), Aitric acid (HNO_3), and Sulphuric acid H_2SO_4 completely ionize in their solutions to give H^+ (H_3O^+) ions and anions ClO_4^-, ClO_3^-, Cl^-, NO_3^-, and HSO_4^-, respectively. Strong bases NaOH, KOH, and $Ca(OH)_2$ also completely ionize to give OH^- ions and Na^+, K^+, and Ca^{2+} ions, respectively. In an acidic solution, $[H^+]$ is greater than $[OH^-]$. For example, in a 1.00 mol/L HCl solution at 298 K, $[H^+] = 1.00$ mol/L, pH = 0.00, $[OH^-] = 10^{-14}$ mol/L.

Weak acids such as formic acid (HCOOH), acetic acid (HCH_3COO), ascorbic acid ($H_2C_6H_6O_6$), oxalic acid ($H_2C_2O_4$), carbonic acid (H_2CO_3), benzoic acid (HC_6H_5COO), malic acid ($H_2C_4H_4O_5$), lactic acid ($HCH_3CH(OH)COO$), and phosphoric acid (H_3PO_4) also ionize in their aqueous solutions, but not completely. The ionization of acetic acid is represented by the equilibrium

$$HCH_3COO(aq) \leftrightarrow H^+(aq) + CH_3COO^-(aq),$$
$$K_a = \frac{[H^+][CH_3COO^-]}{[HCH_3COO]} = 1.75 \times 10^{-5} \text{ at 298 K}$$

where K_a, as defined above, is the *acid dissociation constant*.

The solubility of CO_2 in water increases with partial pressure of CO_2, according to Henry's law. The chemical equilibrium for the dissolution is:

$$H_2O(l) + CO_2(g) \leftrightarrow H_2CO_3(aq)$$
Of course, H_2CO_3 dynamically exchanges H^+ and H_2O with other water molecules, and this weak *diprotic acid* ionizes in two stages with acid dissociation constants K_{a1} and K_{a2}:

$$H_2O + CO_2(aq) \leftrightarrow H^+(aq) + HCO_3^-(aq),$$

$$K_{a1} = 4.30 \times 10^{-7} \text{ at 298 K}$$

$$HCO_3^-(aq) \leftrightarrow H^+(aq) + CO_3^{2-}(aq), \ K_{a2} = 5.61 \times 10^{-11}.$$

Constants K_{a1} and K_{a2} increase as temperature rises, but the solubility of CO_2 decreases. At 298 K, the pH of a solution containing 0.1 mol/L H_2CO_3 is 3.7. At this pH, acidophilic organisms survive and grow, but most pathogenic organisms are neutrophiles, and they cease growing. Soft drinks contain other acids—citric, malic, phosphoric, ascorbic, and others. They lower the pH further.

All three hydrogen ions in phosphoric acid (H_3PO_4) are ionizable, and it is a *triprotic acid*. Acids having more than one dissociable H^+ are called *polyprotic acids*.

NH_3 and many nitrogen-containing compounds are weak bases. The ionization equilibrium of NH_3 in water and the *base dissociation constant K_b* are

$$NH_3 + H_2O \leftrightarrow NH_4O \leftrightarrow NH_4^+(aq) + OH^-(aq),$$
$$K_b = \frac{[H^+][OH^-]}{[NH_4OH]} = 1.70 \times 10^{-5} \text{ at 298 K.}$$

Other weak bases react with H_2O and ionize in a similar way.

The ionization or dissociation constants of inorganic and organic acids and bases are extensive, and they have been tabulated in various books (for example Perrin 1965, 1982, Kortüm et al. 1961).

Titration

Titration is a procedure for quantitative analysis of a solute in a solution by measuring the quantity of a reagent used to completely react with it. This method is particularly useful for the determination of acid or base concentrations. A solution with a known concentration of one reagent is added from a burette to a definite amount of the other. The *end point* is reached when the latter substance is completely consumed by the reagent from the burette, and this is detected by the color change of an indicator or by pH measurements. This method has many applications in food analysis.

The titration of strong acids or bases utilizes the rapid reaction between H^+ and OH^-. The unknown quantity of an acid or base may be calculated from the amount used to reach the end point of the titration.

The variation of pH during the titration of a weak acid using a strong base or a weak base using a strong acid is usually monitored to determine the end point. The plot of pH against the amount of reagent added is a *titration curve*. There are a number of interesting features on a titration curve. Titration of a weak acid HA using a strong base NaOH is based on two rapid equilibria:
$$H^+ + OH^- = H_2O, \ K = \frac{[H_2O]}{K_w} = 5.56 \times 10^{15} \text{ at 298 K.}$$
Figure 5.11. Titration curve of a 0.10 mol/L (or M) weak acid HA ($K_a = 1 \times 10^{-5}$) using a 0.10 mol/L strong base NaOH solution.

As the H^+ ions react with OH^-, more H^+ ions are produced due to the equilibrium

$$HA = H^+ + A^-, \quad K_a \text{ (ionization constant of the acid)}.$$

Before any NaOH solution is added, HA is the dominant species; when half of HA is consumed, $[HA] = [A^-]$, which is called the *half equivalence point*. At this point, the pH varies the least when a little H^+ or OH^- is added, and the solution at this point is the *most effective buffer solution,* as we shall see later. The pH at this point is the same as the pK_a of the weak acid. When an equivalent amount of OH^- has been added, the A^- species dominates, and the solution is equivalent to a salt solution of NaA. Of course, the salt is completely ionized.

Polyprotic acids such as ascorbic acid $H_2\text{-}(H_6C_6O_6)$ (Vitamin C; $K_{a1} = 7.9 \times 10^{-5}$, $K_{a2} = 1.6 \times 10^{-12}$) and phosphoric acid H_3PO_4 ($K_{a1} = 6.94 \times 10^{-3}$, $K_{a2} = 6.2 \times 10^{-8}$, K_{a3} 2.1 $\times$ 10^{-12}) have more than one mole of H^+ per mole of acid. A titration curve of these acids will have two and three end points for ascorbic and phosphoric acids, respectively, partly due to the large differences in their dissociation constants (K_{a1}, K_{a2}, etc.). In practice, the third end point is difficult to observe in the titration of H_3PO_4. Vitamin C and phosphoric acids are often used as food additives.

Many food components (e.g., amino acids, proteins, alkaloids, organic and inorganic stuff, vitamins, fatty acids, oxidized carbohydrates, and compounds giving smell and flavor) are weak acids and bases. The pH affects their forms, stability, and reactions. When pH decreases by 1, the concentration of H^+, $[H^+]$, increases 10-fold, accompanied by a 10-fold decrease in $[OH^-]$. The H^+ and OH^- are very active reagents for the esterification and hydrolysis reactions of proteins, carbohydrates, and lipids, as we shall see later. Thus, the acidity, or pH, not only affects the taste of food, it is an important parameter in food processing.

Solutions of Amino Acids

Amino acids have an amino group (NH_3^+), a carboxyl group (COO^-), a H, and a side chain (R) attached to the asymmetric alpha carbon. They are the building blocks of proteins, polymers of amino acids. At a pH called the *isoelectric point*, which depends on the amino acid in question, the dominant species is a *zwitterion*, $RHC(NH_3^+)(COO^-)$, which has a positive and a negative site, but no net charge. For example, the isoelectric point for glycine is pH $= 6.00$, and its dominant species is $H_2C(NH_3^+)COO^-$. An amino acid exists in at least three forms due to the following ionization or equilibria:

$$RHC(NH_3^+)(COOH) = RHC(NH_3^+)(COO^-) + H^+, \quad K_{a1}$$
$$RHC(NH_3^+)(COO^-) = RHC(NH_2)(COO^-) + H^+, \quad K_{a2}.$$

Most amino acids behave like a diprotic acid with two dissociation constants, K_{a1} and K_{a2}. A few amino acids have a third ionizable group in their side chains.

Among the 20 common amino acids, the side chains of eight are nonpolar, and those of seven are polar, containing —OH, >C=O, or —SH groups. Aspartic and glutamic acid contain acidic —COOH groups in their side chains, whereas arginine, histidine, and lysine contain basic —NH or —NH_2 groups. These have four forms due to adding or losing protons at different pH values of the solution, and they behave as triprotic acids. For example, aspartic acid $[Asp = (COOH)CH_2C(NH_3^+)(COO^-)]$ has these forms:

$$AspH^+ = Asp + H^+$$
$$Asp = Asp^- + H^+$$
$$Asp^- = Asp^{2-} + H^+$$
Proteins, amino acid polymers, can accept or provide several protons as the pH changes. At its *isoelectric point* (a specific pH), the protein has no net charge and is least soluble because electrostatic repulsion between its molecules is lowest, and the molecules coalesce or precipitate, forming a solid or gel.

Solutions of Salts

Salts consist of positive and negative ions, and these ions are hydrated in their solutions. Positive, hydrated ions such as $Na(H_2O)_6^+$, $Ca(H_2O)_8^{2+}$, and $Al(H_2O)_6^{3+}$ have six to eight water molecules around them. Figure 5.12 is a sketch of the interactions of water molecules with ions. The water molecules point the negative ends of their dipoles toward positive ions, and their positive ends toward negative ions. Molecules in the hydration sphere constantly and dynamically exchange with those around them. The number and lifetimes of hydrated water molecules have been studied by various methods. These studies reveal that the hydration sphere is one layer deep, and the lifetimes of these hydrated water molecules are in the order of picoseconds (10^{-12} seconds). The larger negative ions also interact with the polar water molecules, but not as strongly as do cations. The presence of ions in the solution changes the ordering of water molecules even if they are not in the first hydration sphere.

The hydration of ions releases energy, but breaking up ions from a solid requires energy. The amount of energy needed
Figure 5.12. The first hydration sphere of most cations $M(H_2O)_6^+$, and anions $X(H_2O)_6^{-1}$. Small water molecules are below the plane containing the ions, and large water molecules are above the plane.

depends on the substance, and for this reason, some substances are more soluble than others. Natural waters in oceans, streams, rivers, and lakes are in contact with minerals and salts. The concentrations of various ions depend on the solubility of salts (Moeller and O'Connor 1972) and the contact time.

All salts dissolved in water are completely ionized, even those formed in the reaction between weak acids and weak bases. For example, the common food preservative sodium benzoate (NaC_6H_5COO) is a salt formed between a strong base NaOH and weak benzoic acid ($K_a = 6.5 \times 10^{-5}$). The benzoate ions, $C_6H_5COO^-$, in the solution react with water to produce OH^- ions giving a slightly basic solution:

$$C_6H_5COO^- + H_2O \leftrightarrow C_6H_5COOH + OH^-,$$

$$K = 1.6 \times 10^{-10}, \text{ at } 298 \text{ K}.$$
Ammonium bicarbonate, NH_4HCO_3, was a leavening agent before modern baking powder was popular. It is still called for in some recipes. This can be considered a salt formed between the weak base NH_4OH and the weak acid H_2CO_3. When NH_4HCO_3 dissolves in water, the ammonium and bicarbonate ions react with water:

$$NH_4^+ + H_2O \leftrightarrow NH_3(aq) + H_3O^+, \ K = 5.7 \times 10^{-10},$$

at 298 K

$$HCO_3^- + H_2O \leftrightarrow H_2CO_3 + OH^-, \ K = 2.3 \times 10^{-8}, \text{ at } 298 \text{ K}$$

$$H_2CO_3 = H_2O + CO_2(g).$$

Upon heating, NH_3 and carbon dioxide (CO_2) become gases for the leavening action. Thus, during the baking or frying process, NH_3 is very pungent and unpleasant. When sodium bicarbonate is used, only CO_2 causes the dough to rise. Phosphoric acid, instead of NH_4^+, provides the acid in baking powder.

Buffer Solutions

A solution containing a weak acid and its salt or a weak base and its salt is a buffer solution, since its pH changes little when a small amount acid or base is added. For example, nicotinic acid ($HC_6H_4NO_2$, niacin, a food component) is a weak acid with $K_a = 1.7 \times 10^{-5}$ ($pK_a = -\log_{10}K_a = 4.76$):
$$HC_6H_4NO_2 = H^+ + C_6H_4NO_2^-,$$

$$K_a = \frac{[H^+][C_6H_4NO_2^-]}{[HC_6H_4NO_2]}$$

$$pH = pK_a + \log_{10}\left\{\frac{[C_6H_4NO_2^-]}{[HC_6H_4NO_2]}\right\}$$

(Henderson-Hesselbalch equation).

In a solution containing niacin and its salt, $[C_6H_4NO_2^-]$ is the concentration of the salt, and $[HC_6H_4NO_2]$ is the concentration of niacin. The pair, $HC_6H_4NO_2$ and $C_6H_4NO_2^-$, are called **conjugate acid and base**, according to the Bronsted-Lowry definition for acids and bases. So, for a general acid and its conjugate base, the pH can be evaluated using the Henderson-Hesselbalch equation:

$$pH = pK_a = \log_{10}\left\{\frac{[\text{base}]}{[\text{acid}]}\right\}$$

(Henderson-Hesselbalch Equation).

Adding H^+ converts the base into its conjugate acid, and adding OH^- converts the acid into its conjugate base. Adding acid and base changes the ratio [base]/[acid], causing a small change in the pH if the initial ratio is close to 1.0. Following this equation, the most effective buffer solution for a desirable pH is to use an acid with a pK_a value similar to the desired pH value and to adjust the concentration of the salt and acid to obtain the ratio that gives the desired pH. For example, the pK_a for $H_2PO_4^-$ is 7.21, and mixing KH_2PO_4 and K_2HPO_4 in the appropriate ratio will give a buffer solution with pH 7. However, more is involved in the art and science of making and standardizing buffer solutions. For example, the ionic strength must be taken into account.

The pH of blood from healthy persons is 7.4. The phosphoric acid and bicarbonate ions in blood and many other soluble

biomaterials in the intercellular fluid play a buffering role in keeping the pH constant. The body fluids are very complicated buffer solutions, because each conjugate pair in the solution has an equilibrium of its own. These equilibria plus the equilibrium due to the self-ionization of water stabilize the pH of the solution. Buffer solutions abound in nature: milk, juice, soft drinks, soup, fluid contained in food, and water in the ocean, for example.

Hydrophilic and Hydrophobic Effects

The *hydrophilic effect* refers to the hydrogen bonding, polar-ionic and polar–polar interactions with water molecules, which lower the energy of the system and make ionic and polar substances soluble. The lack of strong interactions between water molecules and lipophilic molecules or the nonpolar portions of amphiphilic molecules is called the *hydrophobic effect*, a term coined by Charles Tanford (1980).

When mixed with water, ionic and polar molecules dissolve and disperse in the solution, whereas the nonpolar or hydrophobic molecules huddle together, forming groups. At the proper temperature, groups of small and nonpolar molecules surrounded by water cages form stable phases called *hydrates* or *clathrates*. For example, the clathrate of methane forms stable crystals at temperatures below 300 K (Sloan 1998). The hydrophobic effect causes the formation of micelles and the folding of proteins in enzymes so that the hydrophobic parts of the long chain huddle together on the inside, exposing the hydrophilic parts to the outside to interact with water.

Hydrophilic and hydrophobic effects together stabilize three-dimensional structures of large molecules such as enzymes, proteins, and lipids. Hydrophobic portions of these molecules stay together, forming pockets in globular proteins. These biopolymers minimize their hydrophobic surface to reduce their interactions with water molecules. Biological membranes often have proteins bonded to them, and the hydrophilic portions extend to the intra- and intercellular aqueous solutions. These membrane-bound proteins often transport specific nutrients in and out of cells. For example, water, amino acid, and potassium-sodium ion transporting channels are membrane-bound proteins (Garrett and Grisham 2002).

Hydrophilic and hydrophobic effects, together with the ionic interaction, cause long-chain proteins called *enzymes* to fold in specific conformations (three-dimensional structures) that catalyze specific reactions. The pH of the medium affects the charges of the proteins. Therefore, the pH may alter enzyme conformations and affect their functions. At a specific pH, some enzymes consist of several subunits that aggregate into one complex structure in order to minimize the hydrophobic surface in contact with water. Thus, the chemistry of water is intimately mingled with the chemistry of life.

During food processing, proteins are denatured by heat, acid, base, and salt. These treatments alter the conformation of the proteins and enzymes. Denatured proteins lose their life-maintaining functionality. Molecules containing hydrophilic and hydrophobic parts are emulsifiers that are widely used in the food industry.

Hydrophilic and hydrophobic effects cause nonpolar portions of phospholipids, proteins, and cholesterol to assemble into micelles and bilayers, or biological membranes (Sloan 1998). The membrane conformations are stable due to their low energy, and they enclose compartments with components to perform biological functions. Proteins and enzymes attached to the membranes communicate and transport nutrients and wastes for cells, keeping them alive and growing.

Hard Waters and Their Treatments

Waters containing dissolved CO_2 (same as H_2CO_3) are acidic due to the equilibria
$$H^+(aq) + HCO_3^-(aq) \leftrightarrow H_2CO_3(aq) \Delta H_2O + CO_2(g)$$

$$HCO_3^-(aq) \leftrightarrow H^+(aq) + CO_3^{2-}(aq).$$
Acidic waters dissolve $CaCO_3$ and $MgCO_3$, and waters containing Ca^{2+}, Mg^{2+}, HCO_3^-, and CO_3^{2-} are *temporary hard waters,* as the hardness is removable by boiling, which reduces the solubility of CO_2. When CO_2 is driven off, the solution becomes less acidic due to the above equilibria. Furthermore, reducing the acidity increases the concentration of CO_3^{2-}, and solids $CaCO_3$ and $MgCO_3$ precipitate:

$$Ca^{2+}(aq) + CO_3^{2-}(aq) \leftrightarrow CaCO_3(s)$$

$$Mg^{2+}(aq) + CO_3^{2-}(aq) \leftrightarrow MgCO_3(s).$$
Water containing less than 50 mg/L of these substances is considered soft; 50–150 mg/L moderately hard; 150–300 mg/L hard; and more than 300 mg/L very hard.

For water softening by the *lime treatment*, the amount of dissolved Ca^{2+} and Mg^{2+} is determined first; then an equal number of moles of lime, $Ca(OH)_2$, is added to remove them, by these reactions:

$$Mg^{2+} + Ca(OH)_2(s) \leftrightarrow Mg(OH)_2(s) + Ca^{2+}$$

$$Ca^{2+} + 2HCO_3^- + Ca(OH)_2(s) \leftrightarrow 2CaCO_3(s) + 2H_2O.$$

Permanent hard waters contain sulfate (SO_4^{2-}), Ca^{2+}, and Mg^{2+} ions. Calcium ions in the sulfate solution can be removed by adding sodium carbonate due to the reaction:

$$Ca^{2+} + Na_2CO3 \leftrightarrow CaCO_3(s) + 2Na^+.$$

Hard waters cause scales or deposits to build up in boilers, pipes, and faucets—problems for food and other industries. Ion exchange using resins or zeolites is commonly used to soften hard waters. The calcium and magnesium ions in the waters are taken up by the resin or zeolite that releases sodium or hydrogen ions back to the water. Alternatively, when pressure is applied to a solution, water molecules, but not ions, diffuse through the semipermeable membranes. This method, called *reverse osmosis*, has been used to soften hard waters and desalinate seawater.

However, water softening replaces desirable calcium and other ions with sodium ions. Thus, soft waters are not suitable for drinking. Incidentally, calcium ions strengthen the gluten proteins in dough mixing. Some calcium salts are added to the dough by bakeries to enhance bread quality.

Ionic Strength and Solubility of Foodstuff

Ions are attracted to charged or polar sites of large biomolecules. Cations strongly interact with large molecules such as proteins. At low concentrations, they may neutralize charges on large organic molecules, stabilizing them. At high concentrations, ions compete with large molecules for water and destabilize them, resulting in decreased solubility. The concentration of electrolytes affects the solubility of foodstuffs.

One of the criteria for concentration of electrolytes is *ionic strength*, I, which is half of the sum (Σ) of all products of the concentration (C_i) of the ith ion and the square of its charge (Z_i^2):

$$I = \frac{1}{2}\Sigma C_i Z_i^2.$$

However, solubility is not only a function of ionic strength; it also depends very much on the anions involved.

The *salting-in phenomenon* refers to increases of protein solubility with increased concentrations of salt at low ionic strength. The enhancement of broth flavor by adding salt may be due to an increase of soluble proteins or amino acids in it. At high ionic strength, however, the solubilities of some proteins decrease; this is the *salting-out phenomenon*. Biochemists often use potassium sulfate, K_2SO_4, and ammonium sulfate, $(NH_4)_2SO_4$, for the separation of amino acids or proteins because the sulfate ion is an effective salting-out anion. The sulfate ion is a *stabilizer*, because the precipitated proteins are stable. Table salt is not an effective salting-out agent. Damodaran (1996) and Voet and Voet (1995) discuss these phenomena in much more detail.

WATER AS REAGENT AND PRODUCT

Water is the product from the oxidation of hydrogen, and the standard cell potential (ΔE^o) for the reaction is 1.229 V:

$$2H_2(g) + O_2(g) = 2H_2O(l), \ \Delta E^o = 1.229 \text{ V}.$$
Actually, all hydrogen in any substance produces water during combustion and oxidation. On the other hand, water provides protons (H^+), hydroxide ions (OH^-), hydrogen atoms (H), oxygen atoms (O), and radicals (H·, ·OH) as reagents. The first two of these (H^+ and OH^-) also exhibit acid-base properties, as described earlier. Acids and bases promote hydrolysis and condensation reactions.

In *esterification* and *peptide synthesis*, two molecules are joined together, or condensed, releasing a water molecule. On the other hand, water breaks ester, peptide, and glycosidic bonds in a process called *hydrolysis*.

Esterification, Hydrolysis, and Lipids

Organic acids and various alcohols present in food react to yield esters in aqueous solutions. Esters, also present in food, hydrolyze to produce acids and alcohols. Water is a reagent and a product in these reversible equilibria. Figure 5.13 shows the Fisher esterification and hydrolysis reactions and the role of water in the series of intermediates in these equilibria. In general,

Figure 5.13. Esterification and hydrolysis in aqueous solutions.

esterification is favored in acidic solutions, and hydrolysis is favored in neutral and basic solutions.

The protonation of the slightly negative carbonyl oxygen ($>C=O$) of the carboxyl group ($C(=O)OH$) polarizes the $C=O$ bond, making the carbon atom positive, to attract the alcohol group $R'OH$. Water molecules remove protons and rearrange the bonds in several intermediates for the simple overall reaction

$$RC(=O)OH + HOR' \leftrightarrow RC(=O)OR' + H_2O$$
In basic solutions, the OH^- ions are attracted to the slightly positive carbon of the carbonyl group. The hydrolysis is the reverse of esterification.

Hydrolysis of glycerol esters (glycerides: fat and oil) in basic solutions during soap making is a typical example of hydrolysis. Triglycerides are hydrophobic, but they can undergo partial hydrolysis to become amphiphilic diglycerides or monoglycerides. Esterification and hydrolysis are processes in metabolism.

Lipids, various water-insoluble esters of fatty acids, include glycerides, phospholipids, glycolipids, and cholesterol. Oils and fats are mostly triglycerides, which is a glycerol molecule ($CH_2OH–CHOH–CH_2OH$) esterified with three fatty acids [$CH_3(–CH_2)_nCOOH$, $n = 8–16$]. Some of the triglycerides are partially hydrolyzed in the gastrointestinal tract before absorption, but most are absorbed with the aid of bile salts, which emulsify the oil and facilitate its absorption. Many animals biosynthesize lipids when food is plentiful, as lipids provide the highest amount of energy per unit mass. Lipids, stored in fat cells, can be hydrolyzed, and upon further oxidation, they produce lots of energy and water. Some animals utilize fat for both energy and water to overcome the limitation of food and water supplies during certain periods of their lives.
Figure 5.14. Hydrolysis and peptide-bond formation (polymerization).

Catalyzed by enzymes, esterification, and hydrolysis in biological systems proceed at much faster rates than when catalyzed by acids and bases.

WATER IN DIGESTION AND SYNTHESES OF PROTEINS

The digestion and the formation of many biopolymers (such as proteins and carbohydrates) as well as the formation and breakdown of lipids and esters involve reactions very similar to those of esterification and hydrolysis.

The digestion of proteins, polymers of amino acids, starts with chewing, followed by hydrolysis with the aid of protein-cleaving enzymes (proteases) throughout the gastrointestinal tract. Then, the partially hydrolyzed small peptides and hydrolyzed individual amino acids are absorbed in the intestine. Water is a reagent in these hydrolyses (Fig. 5.14).

The *deoxyribonucleic acids* (DNAs) store the genetic information, and they direct the synthesis of *messenger ribonucleic acids* (mRNAs), which in turn direct the protein synthesis machinery to make various proteins for specific body functions and structures. This is an oversimplified description of the biological processes that carry out the polymerization of amino acids.

Proteins and amino acids also provide energy when fully oxidized, but carbohydrates are the major energy source in normal diets.

WATER IN DIGESTION AND SYNTHESIS OF CARBOHYDRATES

On earth, water is the most abundant inorganic compound, whereas carbohydrates are the most abundant class of organic compounds. Carbohydrates require water for their synthesis and provide most of the energy for all life on earth. They are also part

of the glycoproteins and the genetic molecules of DNA. *Carbohydrates* are compounds with a deceivingly simple general formula $(CH_2O)_n$, $n \geq 3$, that appears to be made up of carbon and water, but although their chemistry fills volumes of thick books and more, there is still much for carbohydrate chemists to discover.

Energy from the sun captured by plants and organisms converts CO_2 and water to high-energy carbohydrates,

$$6CO_2 + 12H_2O^* \rightarrow (CH_2O)_6 + 6H_2O + 6O_2^*$$

The stars (*) indicate the oxygen atoms from water released as oxygen gas (O_2^*). Still, this is an oversimplified equation for photosynthesis, but we do not have room to dig any deeper. The product $(CH_2O)_6$ is a *hexose*, a six-carbon simple sugar, or *monosaccharide,* that can be fructose, glucose, or another simple sugar. Glucose is the most familiar simple sugar, and its most common structure is a cyclic structure of the chair form. In glucose, all the OH groups around the ring are at the equatorial positions, whereas the small H atoms are at the axial locations (Fig. 5.15). With so many OH groups per molecule, glucose molecules are able to form several hydrogen bonds with water molecules, and thus most monosaccharides are soluble in water.

The *disaccharides* sucrose, maltose, and lactose have two simple sugars linked together, whereas starch and fiber are polymers of many glucose units. A disaccharide is formed when two OH groups of separate monosaccharides react to form an –O– link, called a *glycosidic bond*, after losing a water molecule:

$$C_6H_{12}O_6 + C_6H_{12}O_6 = C_6H_{11}O_5\text{–O–}C_6H_{11}O_5 + H_2O.$$

Disaccharides are soluble in water due to their ability to form many hydrogen bonds.

Plants and animals store glucose as long-chain *polysaccharides* in *starch* and *glycogen*, respectively, for energy. Starch is divided into amylose and amylopectin. *Amylose* consists of linear chains, whereas *amylopectin* has branched chains. Due to the many interchain hydrogen bonds in starch, hydrogen bonding to water molecules develops slowly. Small starch molecules are soluble in water. Suspensions of large starch molecules thicken

**Figure 5.15.** Chair form cyclic structure of glucose $C_6H_{12}O_6$. For glucose, all the OH groups are in the equatorial position, and these are possible H-donors for hydrogen bonding with water molecules. They are also possible sites to link to other hexoses.

soup and gravy, and starch is added to food for desirable texture and appearance. Water increases the molecular mobility of starch, and starch slows the movement of water molecules. Food processors are interested in a quantitative relationship between water and starch and the viscosity of the suspension.

Glycogen, animal starch, is easily hydrolyzed to yield glucose, which provides energy when required. In the hydrolysis of polysaccharides, water molecules react at the glycosidic links. Certain enzymes catalyze this reaction, releasing glucose units one by one from the end of a chain or branch.

Polysaccharide chains in cellulose are very long, 7000–15,000 monosaccharides, and interchain hydrogen bonds bind them into fibers, which further stack up through interfiber hydrogen bonds. Many interchain hydrogen bonds make the penetration of water molecules between chains a time-consuming process. Heating speeds up the process.

WATER, MINERALS, AND VITAMINS

Most minerals are salts or electrolytes. These are usually ingested as aqueous solutions of electrolytes, discussed earlier. Ions (Ca^{2+}, Mg^{2+}, Na^+, K^+, Fe^{2+}, Zn^{2+}, Cu^{2+}, Mn^{2+}, Cl^-, I^-, S^{2-}, Se^{2-}, $H_2PO_4^-$, etc.) present in natural water are leached from the ground. Some of them are also present in food, because they are essential nutrients for plants and animals that we use as food. A balance of electrolytes in body fluid must be maintained. Otherwise, shock or fainting may develop. For example, the drinking water used by sweating athletes contains the proper amount of minerals. In food, mineral absorption by the body may be affected by the presence of other molecules. For example, vitamin D helps the absorption of calcium ions.

Small amounts of a group of organic compounds not synthesized by humans, but essential to life, are called vitamins; their biochemistry is very complicated and interesting; many interact with enzymes, and others perform vital functions by themselves. Regardless of their biological function and chemical composition, vitamins are divided into water-soluble and fat-soluble groups. This division, based on polarity, serves as a guide for food processing. For example, food will lose water-soluble vitamins when washed or boiled in water, particularly after cutting (Hawthorne and Kubatova 2002).

The water-soluble vitamins consist of a complex group of vitamin Bs, vitamin C, biotin, lipoic acid, and folic acid. These molecules are either polar or have the ability to form hydrogen bonds. Vitamins A (retinal), D2, D3, E, and K are fat soluble, because major portions of their molecules are nonpolar organic groups.

Vitamin C, L-ascorbic acid or 3-oxo-L-gulofuranolactone, has the simplest chemical formula ($C_6H_8O_6$) among vitamins. This diprotic acid is widely distributed in plants and animals, and only a few vertebrates, including humans, lack the ability to synthesize it.

Vitamin B complex is a group of compounds isolated together in an aqueous solution. It includes thiamine (B1), riboflavin (B2), niacin (or nicotinic acid, B3), pantothenic acid (B5), cyanocobalamin (B12), and vitamin B6 (any form of pyridoxal, pyridoxine, or pyridoxamine). Biotin, lipoic acid, and folic acid are also part of the water-soluble vitamins. These vitamins are part of enzymes or coenzymes that perform vital functions.

FOOD CHEMISTRY OF WATER

Water ingestion depends on the individual, composition of the diet, climate, humidity, and physical activity. A nonexercising adult loses the equivalent of 4% of his or her body weight in water per day (Brody 1999). Aside from ingested water, water is produced during the utilization of food. It is probably fair to suggest that food chemistry is the chemistry of water, since we need a constant supply of water as long as we live.

Technical terms have special meanings among fellow food scientists. Furthermore, food scientists deal with dynamic and nonequilibrium systems, unlike most natural scientists who deal with static and equilibrium systems. There are special concepts and parameters useful only to food scientists. Yet, the fundamental properties of water discussed above lay a foundation for the food chemistry of water. With respect to food, water is a component, solvent, acid, base, and dispersing agent. It is also a medium for biochemical reactions, for heat and mass transfer, and for heat storage.

Food chemists are very concerned with water content and its effects on food. They need reliable parameters for references, criteria, and working objectives. They require various indicators to correlate water with special properties such as perishability, shelf life, mobility, smell, appearance, color, texture, and taste.

WATER AS A COMMON COMPONENT OF FOOD

Water is a food as well as the most common component of food. Even dry foods contain some water, and the degree of water content affects almost every aspect of food: stability, taste, texture, and spoilage.

Most food molecules contain OH, C=O, NH, and polar groups. These sites strongly interact with water molecules by hydrogen bonding and dipole-dipole interactions. Furthermore, dipole-ion, hydrophilic, and hydrophobic interactions also occur between water and food molecules. The properties of hydrogen-bonded water molecules differ from those in bulk water, and they affect the water molecules next to them. There is no clear boundary for affected and unaffected water molecules. Yet it is convenient to divide them into *bound water* and *free water*. This is a vague division, and a consensus definition is hard to reach. Fennema and Tannenbaum (1996) give a summary of various criteria for them, indicating a diverse opinion. However, the concept is useful, because it helps us understand the changes that occur in food when it is heated, dried, cooled, or refrigerated. Moreover, when water is the major ingredient, interactions with other ingredients modify the properties of the water molecules. These aspects were discussed earlier in connection with aqueous solutions.

WATER ACTIVITY

Interactions of water and food molecules mutually change their properties. Water in food is not pure water. Water molecules in

vapor, liquid, and solid phases or in solutions and food react and interchange in any equilibrium system. The tendency to react and interchange with each other is called the *chemical potential*, μ. At equilibrium, the potential of water in all phases and forms must be equal at a given temperature, T. The potential, μ, of the gas phase may be expressed as:

$$\mu = \mu_w + RT \ln(p/p_w),$$

where R is the gas constant (8.3145 J mol^{-1}K^{-1}), p is the partial water vapor pressure, and p_w is the vapor pressure of pure water at T. The ratio p/p_w is called the *water activity a_w* ($= p/p_w$), although this term is also called *relative vapor pressure* (Fennema and Tannenbaum 1996). The difference is small, and for simplicity, a_w as defined is widely used for correlating the stability of foods. For ideal solutions and for most moist foods, a_w is less than unity ($a_w < 1.0$; Troller 1978).

The Clausius-Clapeyron equation, mentioned earlier, correlates vapor pressure, P, heat of phase transition, ΔH, and temperature, T. This same relationship can be applied to water activity. Thus, the plot of $\ln(a_w)$ versus $1/T$ gives a straight line, at least within a reasonable temperature range. Depending on the initial value for a_w or moisture content, the slope differs slightly, indicating the difference in the heat of phase transition due to different water content.

Both water activity and relative humidity are fractions of the pure-water vapor pressure. Water activity can be measured in the same way as humidity. Water contents have a sigmoidal relationship (Fig. 5.16). As water content increases, a_w increases: $a_w = 1.0$ for infinitely dilute solutions, $a_w > 0.7$ for dilute solutions and moist foods, and $a_w < 0.6$ for dry foods. Of course, the precise relationship depends on the food. In general, if the water vapor in the atmosphere surrounding the food is greater than the water activity of the food, water is adsorbed; otherwise, desorption takes place. Water activity reflects the combined effects of water-solute, water-surface, capillary, hydrophilic, and hydrophobic interactions.

Water activity is a vital parameter for food monitoring. A plot of a_w versus water content is called an *isotherm*. However, desorption and adsorption isotherms are different (Fig. 5.16) because this is a nonequilibrium system. Note that isotherms in most other literature plot water content against a_w, the reverse of the axes of Figure 5.16, which is intended to show that a_w is a function of water content.

Water in food may be divided into tightly bound, loosely bound, and nonbound waters. Dry foods contain tightly bound (monolayer) water, and a_w rises slowly as water content increases; but as loosely bound water increases, a_w increases rapidly and approaches 1.0 when nonbound water is present. Crisp crackers get soggy after adsorbing water from moist air, and soggy ones can be dried by heating or exposure to dry air.

Water activity affects the growth and multiplication of microorganisms. When $a_w < 0.9$, growth of most molds is inhibited. Growth of yeasts and bacteria also depends on a_w. Microorganisms cease growing if $a_w < 0.6$. *In a system, all components must be in equilibrium with one another, including all the microorganisms. Every type of organism is a component and a phase of the system, due to its cells or membranes. If the water activity of an organism is lower than that of the bulk food, water will be absorbed, and thus the species will multiply and grow. However, if the water activity of the organism is higher, the organism will dehydrate and become dormant or die.* Thus, it is not surprising that water activity affects the growth of various molds and bacteria. By this token, humidity will have the same effect on microorganisms in residences and buildings. Little packages of drying agent are placed in sealed dry food to reduce vapor pressure and prevent growth of bacteria that cause spoilage.

AQUATIC ORGANISMS AND DRINKING WATER

Life originated in the water or oceans eons ago, and vast populations of the earliest unicellular living organisms still live in water today. Photosynthesis by algae in oceans consumes more CO_2 than the photosynthesis by all plants on land. Diversity of phyla (divisions) in the kingdoms of Fungi, Plantae, and Animalia live in water, ranging from single-cell algae to mammals.

All life requires food or energy. Some living organisms receive their energy from the sun, whereas others get their energy from chemical reactions. For example, the bacteria *Thiobacillus ferrooxidans* derive energy by catalyzing the oxidation of iron sulfide, FeS_2, using water as the oxidant (Barret et al. 1939). Chemical reactions provide energy for bacteria to sustain their lives and to reproduce. Many organisms feed on other organisms, forming a food chain. Factors affecting life in water include minerals, solubility of the mineral, acidity (pH), sunlight, dissolved oxygen level, presence of ions, chemical equilibria, availability of food, and electrochemical potentials of the material, among others.

Water used directly in food processing or as food is *drinking water*, and aquatic organisms invisible to the naked eye can be beneficial or harmful. The *Handbook of Drinking Water Quality* (De Zuane 1997) sets guidelines for water used in

Figure 5.16. Nonequilibrium or hysteresis in desorption and adsorption of water by foodstuff. Arbitrary scales are used to illustrate the concept for a generic pattern.

food services and technologies. Wastewater from the food industry needs treatment, and the technology is usually dealt with in industrial chemistry (Lacy 1992).

When food is plentiful, beneficial and pathogenic organisms thrive. Pathogenic organisms present in drinking water cause intestinal infections, dysentery, hepatitis, typhoid fever, cholera, and other diseases. Pathogens are usually present in waters that contain human and animal wastes that enter the water system via discharge, runoffs, flood, and accidents at sewage treatment facilities. Insects, rodents, and animals can also bring bacteria to the water system (Coler 1989, Percival et al. 2000). Testing for all pathogenic organisms is impossible, but some organisms have common living conditions. These are called *indicator bacteria*, because their absence signifies safety.

WATER AND STATE OF FOOD

When a substance and water are mixed, they mutually dissolve, forming a homogeneous solution, or they partially dissolve in each other, forming solutions and other phases. At ambient pressure, various phases are in equilibrium with each other in isolated and closed systems. The equilibria depend on temperature. A plot of temperature versus composition showing the equilibria among various phases is a *phase diagram* for a two-component system. Phase diagrams for three-component systems are very complicated, and foods consist of many substances, including water. Thus, a strict phase diagram for food is almost impossible. Furthermore, food and biological systems are open, with a steady input and output of energy and substances. Due to time limits and slow kinetics, phases are not in equilibrium with each other. However, the changes follow a definite rate, and these are *steady states*. For these cases, plots of temperature against the composition, showing the existences of states (phases), are called *state diagrams*. They indicate the existence of various phases in multicomponent systems.

Sucrose (sugar, $C_{12}H_{22}O_{11}$) is a food additive and a sweetener. Solutions in equilibrium with excess solid sucrose are saturated, and their concentrations vary with temperature. The saturated solutions contain 64.4 and 65.4% at 0 and 10°C, respectively. The plot of saturated concentrations against temperature is *the equilibrium solubility curve,* ES, in Figure 5.17. The freezing curve, FE, shows the variation of freezing point as a function of temperature. Aqueous solution is in equilibrium with ice Ih along FE. At the *eutectic point,* E, the intersection of the solubility and freezing curves, solids Ih and sucrose coexist with a saturated solution. The eutectic point is the lowest mp of water–sugar solutions. However, viscous aqueous sugar solutions or syrups may exist beyond the eutectic point. These conditions may be present in freezing and tempering (thawing) of food.

Dry sugar is stable, but it spoils easily if it contains more than 5% water. The changes that occur as a sugar solution is chilled exemplify the changes in some food components when foods freeze. Ice Ih forms when a 10% sugar solution is cooled below the freezing point. As water forms Ih, leaving sugar in the solution, the solution becomes more concentrated, decreasing the freezing point further along the FE toward the E. However, when cooled, this solution may not reach equilibrium and yield

Figure 5.17. A sketch showing the phase and state diagram of water-sucrose binary system.

sugar crystals at the eutectic point. Part of the reason for not having sucrose crystals is the high viscosity of the solution, which prevents molecules from moving and orienting properly to crystallize. The viscous solution reaches a glassy or amorphous state at the *glass transition temperature (Tg)*, point G. The glass state is a frozen liquid with extremely high viscosity. In this state, the molecules are immobile. The temperature, Tg, for glass transition depends on the rate of cooling (Angell 2002). The freezing of sugar solution may follow different paths, depending on the experimental conditions.

In lengthy experiments, Young and Jones (1949) warmed glassy states of water-sucrose and observed the warming curve over hours and days for every sample. They observed the eutectic mixture of 54% sucrose (Te = −13.95°C). They also observed the formation of phases $C_{12}H_{22}O_{11} \cdot 2.5H_2O$ and $C_{12}H_{22}O_{11} \cdot 3.5H_2O$ hydrated crystals formed at temperatures higher than the Te, which is for anhydrous sucrose. The water-sucrose binary system illustrates that the states of food components during freezing and thawing can be very complicated. Freshly made ice creams have wonderful texture, and the physics and chemistry of the process are even more interesting.

INTERACTION OF WATER AND MICROWAVE

Wavelengths of microwave range from meters down to a millimeter, their frequencies ranging from 0.3 to 300 GHz. A typical domestic oven generates 2.45 GHz microwaves, wavelength 0.123 m, and energy of photon 1.62×10^{-24} J (10 μeV). For industrial applications, the frequency may be optimized for the specific processes.

Percy L. Spencer (1894–1970), the story goes, noticed that his candy bar melted while he was inspecting magnetron testing at the Raytheon Corporation in 1945. As a further test, he

microwaved popping corns, which popped. A team at Raytheon developed microwave ovens, but it took more than 25 years and much more effort to improve them and make them practical and popular. Years ago, boiling water in a paper cup in a microwave oven without harming the cup amazed those who were used to see water being heated in a fire-resistant container over a stove or fire. Microwaves simultaneously heat all the water in the bulk food.

After the invention of the microwave oven, many offered explanations on how microwaves heat food. Water's high dipole moment and high dielectric constant caused it to absorb microwave energy, leading to an increase in its temperature. Driven by the oscillating electric field of microwaves, water molecules rotate, oscillate, and move about faster, increasing water temperature to sometimes even above its bp. In regions where water has difficulty forming bubbles, the water is overheated. When bubbles suddenly do form in superheated water, an explosion takes place. Substances without dipole moment cannot be heated by microwaves. Therefore, plastics, paper, and ceramics won't get warm. Metallic conductors rapidly polarize, causing sparks due to arcing. The oscillating current and resistance of some metals cause a rapid heating. In contrast, water is a poor conductor, and the heating mechanism is very complicated. Nelson and Datta (2001) reviewed microwave heating in the *Handbook of Microwave Technology for Food Applications*.

Molecules absorb photons of certain frequencies. However, microwave heating is due not only to absorption of photons by the water molecules, but also to a combination of polarization and dielectric induction. As the electric field oscillates, the water molecules try to align their dipoles with the electric field. Crowded molecules restrict one another's movements. The resistance causes the orientation of water molecules to lag behind that of the electric field. Since the environment of the water molecules is related to their resistance, the heating rate of the water differs from food to food and region to region within the same container. Water molecules in ice, for example, are much less affected by the oscillating electric field in domestic microwave ovens, which are not ideal for thawing frozen food. The outer thawed layer heats up quickly, and it is cooked before the frozen part is thawed. Domestic microwave ovens turn on the microwave intermittently or at very low power to allow thermal conduction for thawing. However, microwaves of certain frequencies may heat ice more effectively for tempering frozen food. Some companies have developed systems for specific purposes, including blanching, tempering, drying, and freeze-drying.

The electromagnetic wave form in an oven or in an industrial chamber depends on the geometry of the oven. If the wave forms a standing wave in the oven, the electric field varies according to the wave pattern. Zones where the electric field varies with the largest amplitude cause water to heat up most rapidly, and the nodal zones where there are no oscillations of electric field will not heat up at all. Thus, uniform heating has been a problem with microwave heating, and various methods have been developed to partly overcome this problem. Also, foodstuffs attenuate microwaves, limiting their penetration depth into foodstuff. Uneven heating remains a challenge for food processors and microwave chefs, mostly due to the short duration of microwaving. On the other hand, food is also seldom evenly heated when conventionally cooked.

Challenges are opportunities for food industries and individuals. For example, new technologies in food preparation, packaging, and sensors for monitoring food temperature during microwaving are required. There is a demand for expertise in microwaving food. Industries microwave-blanche vegetables for drying or freezing to take advantage of its energy efficiency, time saving, decreased waste, and retention of water-soluble nutrients. The ability to quickly temper frozen food in retail stores reduces spoilage and permits selling fresh meat to customers.

Since water is the heating medium, the temperature of the food will not be much higher than the boiling point of the aqueous solutions in the food. Microwave heating does not burn food; thus, the food lacks the usual color, aroma, flavor, and texture found in conventional cooking. The outer layer of food is dry due to water evaporation. Retaining or controlling water content in microwaved food is a challenge.

When microwaved, water vapor is continually removed. Under reduced pressure, food dries or freeze-dries at low temperature due to its tendency to restore the water activity. Therefore, microwaving is an excellent means for drying food because of its savings in energy and time. Microwaves are useful for industrial applications such as drying, curing, and baking or parts thereof.

Microwave ovens have come a long way, and their popularity and improvement continue. Food industry and consumer attitudes about microwavable food have gone up and down, often due to misconceptions. Microwave cooking is still a challenge. The properties of water affect cooking in every way. Water converts microwave energy directly into heat, attenuates microwave radiation, transfers heat to various parts of the foodstuff, affects food texture, and interacts with various nutrients. All properties of water must be considered in order to take advantage of microwave cooking.

WATER RESOURCES AND THE HYDROLOGICAL CYCLE

Fresh waters are required to sustain life and maintain living standards. Therefore, fresh waters are called *water resources*. Environmentalists, scientists, and politicians have sounded alarms about limited water resources. Such alarms appear unwarranted because the earth has so much water that it can be called a water planet. Various estimates of global water distribution show that about 94% of earth's water lies in the oceans and seas. These salt waters sustain marine life and are ecosystems in their own right, but they are not fresh waters that satisfy human needs. Of the remaining 6%, most water is in solid form (at the poles and in high mountains before the greenhouse effect melts them) or underground. Less than 1% of earth's water is in lakes, rivers, and streams, and waters from these sources flow into the seas or oceans. A fraction of 1% remains in the atmosphere, mixed with air (Franks 2000).

A human may drink only a few liters of water in various forms each day, but ten times more water is required for domestic usages such as washing and food preparation. A further equal

amount is needed for various industries and social activities that support individuals. Furthermore, much more is required for food production, maintaining a healthy environment, and supporting lives in the ecosystems. Thus, one human may require more than 1000 L of water per day. In view of these requirements, a society has to develop policies for managing water resources both near and far as well as in the short and long terms. This chapter has no room to address the social and political issues, but facts are presented for readers to formulate solutions to these problems, or at least to ask questions regarding them. Based on these facts, is scarcity of world water resources a reality or not?

A major threat to water resources is climate change, because climate and weather are responsible for the *hydrologic cycle* of salt and fresh waters. Of course, human activities influence the climate in both short and long terms.

Based on the science of water, particularly its transformations among solid, liquid, and vapor phases under the influence of energy, we easily understand that heat from the sun vaporizes water from the ocean and land alike. Air movement carries the moisture (vapor) to different places than those from which it evaporated. As the vapor ascends, cooling temperature condenses the vapor into liquid drops. Cloud and rain eventually develop, and rain erodes, transports, shapes the landscape, creates streams and rivers, irrigates, and replenishes water resources. However, too much rain falling too quickly causes disaster in human life. On the other hand, natural water management for energy and irrigation has brought prosperity to society, easing the effects on humans of droughts and floods, when water does not arrive at the right time and place.

Water is a resource. Competition for this resource leads to "water war." Trade in food and food aid is equivalent to flow of water, because water is required for food production. Food and water management, including wastewater treatment, enable large populations to concentrate in small areas. Urban dwellers take these commodities for granted, but water enriches life both physically and mentally.

6
Enzyme Classification and Nomenclature

H. Ako and W. K. Nip

INTRODUCTION

Before 1961, researchers reported on enzymes or enzymatic activities with names of their own preference. This situation caused confusion to others as various names could be given to the same enzyme. In 1956, the International Union of Biochemistry (IUB, later changed to International Union of Biochemistry and Molecular Biology, IUBMB) created the International Commission on Enzymes in consultation with the International Union of Pure and Applied Chemistry (IUPAC) to look into this situation. This Commission (now called the Nomenclature Committee of the IUBMB, NC-IUBMB) subsequently recommended classifying enzymes into six divisions (classes) with subclasses and sub-subclasses. General rules and guidelines were also established for classifying and naming enzymes. Each enzyme accepted to the Enzyme List was given a recommended name (trivial or working name; now called the common name), a systematic name, and an Enzyme Commission, or Enzyme Code (EC) number. The enzymatic reaction is also provided. A common name (formerly called recommended name) is assigned to each enzyme. This is normally the name most widely used for that enzyme, unless that name is ambiguous or misleading. A newly discovered enzyme can be given a common name and a systematic name, but not the EC number, by the researcher. EC numbers are assigned only by the authority of the NC-IUBMB.

The first book on enzyme classification and nomenclature was published in 1961. Some critical updates were announced as newsletters in 1984 (IUPAC-IUB and NC-IUB Newsletters 1984). The last (sixth) revision was published in 1992. Another update in electronic form was published in 2000 (Boyce and Tipton 2000). With the development of the Internet, most updated information on enzyme classification and nomenclature is now available through the website of the IUBMB (http://www.chem.qmul.ac.uk/iubmb/enzyme.html). This chapter should be considered as an abbreviated version of enzyme classification and nomenclature, with examples of common enzymes related to food processing. Readers should visit the IUBMB enzyme nomenclature website for the most up-to-date details on enzyme classification and nomenclature.

CLASSIFICATION AND NOMENCLATURE OF ENZYMES

General Principles

- *First principle*: Names purporting to be names of enzymes, especially those ending in -*ase* should be used only for single enzymes, that is, single catalytic entities. They should not be applied to systems containing more than one enzyme.
- *Second principle*: Enzymes are classified and named according to the reaction they catalyze.
- *Third principle*: Enzymes are divided into groups on the basis of the type of reactions catalyzed, and this, together

with the name(s) of the substrate(s), provides a basis for determining the systematic name and EC number for naming individual enzymes.

COMMON AND SYSTEMATIC NAMES

- The common name (recommended, trivial, or working name) follows immediately after the EC number.
- While the common name is normally that used in the literature, the systematic name, which is formed in accordance with definite rules, is more precise chemically. It should be possible to determine the reaction catalyzed from the systematic name alone.

SCHEME OF CLASSIFICATION AND NUMBERING OF ENZYMES

The first EC, in its report in 1961, devised a system for the classification of enzymes that also serves as a basis for assigning EC numbers to them. These code numbers (prefixed by EC), which are now widely in use, contain four elements separated by periods (e.g., 1.1.1.1), with the following meaning:

1. The first number shows to which of the six divisions (classes) the enzyme belongs.
2. The second figure indicates the subclass.
3. The third figure gives the sub-subclass.
4. The fourth figure is the serial number of the enzyme in its sub-subclass.

The main classes are as follows:

- *Class 1*: Oxidoreductases (dehydrogenases, reductases, or oxidases).
- *Class 2*: Transferases.
- *Class 3*: Hydrolases.
- *Class 4*: Lyases.
- *Class 5*: Isomerases (racemases, epimerases, cis-trans-isomerases, isomerases, tautomerases, mutases, cycloisomerases).
- *Class 6*: Ligases (synthases).

Class 1: Oxidoreductases

Enzymes catalyzing oxidoreductions belong to this class. The reactions are of the form $AH_2 + B = A + BH_2$ or $AH_2 + B^+ = A + BH + H^+$. The substrate oxidized is regarded as the hydrogen or electron donor. All reactions within a particular sub-subclass are written in the same direction. The classification is based on the order "donor:acceptor oxidoreductase." The common name often takes the form "substrate dehydrogenase," wherever this is possible. If the reaction is known to occur in the opposite direction, this may be indicated by a common name of the form "acceptor reductase" (e.g., the common name of EC 1.1.1.9 is D-xylose reductase). "Oxidase" is used only in cases where O_2 is an acceptor. Classification is difficult in some cases because of the lack of specificity toward the acceptor.

Class 2: Transferases

Transferases are enzymes transferring a group (e.g., the methyl group or a glycosyl group), from one compound (generally regarded as donor) to another compound (generally regarded as acceptor). The classification is based on the scheme "donor:acceptor group transferase." The common names are normally formed as "acceptor grouptransferase." In many cases, the donor is a cofactor (coenzyme) carrying the group to be transferred. The aminotransferases constitute a special case (subclass 2.6): the reaction also involves an oxidoreduction.

Class 3: Hydrolases

These enzymes catalyze the hydrolysis of various bonds. Some of these enzymes pose problems because they have a very wide specificity, and it is not easy to decide if two preparations described by different authors are the same, or if they should be listed under different entries.

While the systematic name always includes "hydrolase," the common name is, in most cases, formed by the name of the substrate with the suffix *-ase*. It is understood that the name of this substrate with the suffix means a hydrolytic enzyme. The peptidases, subclass 3.4, are classified in a different manner from other enzymes in this class.

Class 4: Lyases

Lyases are enzymes cleaving C–C, C–O, C–N, and other bonds by means other than hydrolysis or oxidation. They differ from other enzymes in that two substrates are involved in one reaction direction, but only one in the other direction. When acting on the single substrate, a molecule is eliminated, leaving an unsaturated residue. The systematic name is formed according to "substrate group-lyase." In common names, expressions like decarboxylase, aldolase, and so on are used. "Dehydratase" is used for those enzymes eliminating water. In cases where the reverse reaction is the more important, or the only one to be demonstrated, "synthase" may be used in the name.

Class 5: Isomerase

These enzymes catalyze changes within one molecule.

Class 6: Ligases

Ligases are enzymes catalyzing the joining of two molecules with concomitant hydrolysis of the diphosphate bond in ATP or a similar triphosphate. The bonds formed are often high-energy bonds. "Ligase" is commonly used for the common name, but in a few cases, "synthase" or "carboxylase" is used. Use of the term "synthetase" is discouraged.

GENERAL RULES AND GUIDELINES FOR CLASSIFICATION AND NOMENCLATURE OF ENZYMES

Table 6.1 shows the classification of enzymes by class, subclass, and sub-subclass, as suggested by the Nomenclature Committee

Table 6.1. Classification of Enzymes by Class, Subclass, and Sub-subclass[a]

1. Oxidoreductases
    - 1.1. *Acting on the CH–OH group of donors*
        - 1.1.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.1.2   With a cytochrome as acceptor
        - 1.1.3   With oxygen as acceptor
        - 1.1.4   With a disulfide as acceptor
        - 1.1.5   With a quinone or similar compound as acceptor
        - 1.1.99   With other acceptors
    - 1.2. *Acting on the aldehyde or oxo group of donors*
        - 1.2.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.2.2   With a cytochrome as acceptor
        - 1.2.3   With oxygen as acceptor
        - 1.2.4   With a disulfide compound as acceptor
        - 1.2.7   With an iron–sulfur protein as acceptor
        - 1.2.99   With other acceptors
    - 1.3. *Acting on the CH–CH group of donors*
        - 1.3.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.3.2   With a cytochrome as acceptor
        - 1.3.3   With oxygen as acceptor
        - 1.3.5   With a quinone or related compound as acceptor
        - 1.3.6   With an iron–sulfur protein as acceptor
        - 1.3.99   With other acceptor
    - 1.4. *Acting on the CH–NH$_2$ of donors*
        - 1.4.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.4.2   With a cytochrome as acceptor
        - 1.4.3   With oxygen as acceptor
        - 1.4.4   With a disulfide as acceptor
        - 1.4.7   With an iron–sulfur protein as acceptor
        - 1.4.99   With other acceptors
    - 1.5. *Acting on the CH–NH group of donors*
        - 1.5.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.5.3   With oxygen as acceptor
        - 1.5.4   With disulfide as acceptor
        - 1.5.5   With a quinone or similar compound as acceptor
        - 1.5.8   With a flavin as acceptor
        - 1.5.99   With other acceptors
    - 1.6. *Acting on NADH or NADPH*
        - 1.6.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.6.2   With a heme protein as acceptor
        - 1.6.3   With oxygen as acceptor
        - 1.6.4   With a disulfide compound as acceptor
        - 1.6.5   With a quinone or similar compound as acceptor
        - 1.6.6   With a nitrogenous group as acceptor
        - 1.6.8   With a flavin as acceptor
        - 1.6.99   With other acceptors
    - 1.7. *Acting on other nitrogenous compounds as donors*
        - 1.7.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.7.2   With a cytochrome as acceptor
        - 1.7.3   With oxygen as acceptor
        - 1.7.7   With an iron–sulfur protein as acceptor
        - 1.7.99   With other acceptors
    - 1.8. *Acting on a sulfur group of donors*
        - 1.8.1   With NAD^+ or $NADP^+$ as acceptor
        - 1.8.2   With a cytochrome as acceptor
        - 1.8.3   With oxygen as acceptor
        - 1.8.4   With a disulfide as acceptor

(Continued)

Table 6.1. *(Continued)*

1.8.5	With a quinone or related compound as acceptor
1.8.7	With an iron–sulfur protein as acceptor
1.8.98	With other, known, acceptors
1.8.99	With other acceptors
1.9.3	With oxygen as acceptor
1.9.5	With a nitrogenous group as acceptor
1.9.99	With other acceptors

1.10. Acting on diphenols and related substances as donors

1.10.1	With NAD^+ or $NADP^+$ as acceptor
1.10.2	With a cytochrome as acceptor
1.10.3	With oxygen as acceptor
1.10.99	With other acceptors

1.11. Acting on hydrogen peroxide as acceptor

1.11.1	The peroxidases

1.12. Acting on hydrogen as donor

1.12.1	With NAD^+ or $NADP^+$ as acceptor
1.12.2	With a cytochrome as acceptor
1.12.5	With a quinone or similar compound as acceptor
1.12.7	With an iron–sulfur protein as acceptor
1.12.98	With other known acceptors
1.12.99	With other acceptors

1.13. Acting on single donors with incorporation of molecular oxygen (oxygenases)

1.13.11	With incorporation of two atoms of oxygen
1.13.12	With incorporation of one atom of oxygen (internal monoxygenase or internal mixed-function oxidases)
1.13.99	Miscellaneous

1.14. Acting on paired donors with incorporation of molecular oxygen

1.14.11	With 2-oxoglutarate as one donor, and incorporation of one atom of oxygen into both donors
1.14.12	With NADH or NADPH as one donor, and incorporation of two atoms of oxygen into one donor
1.14.13	With NADH or NADPH as one donor, and incorporation of one atom of oxygen
1.14.14	With reduced flavin or flavoprotein as one donor, and incorporation of one atom of oxygen
1.14.15	With reduced iron–sulfur protein as one donor, and incorporation of one atom of oxygen
1.14.16	With reduced pteridine as one donor, and incorporation of one atom of oxygen
1.14.17	With reduced ascorbate as one donor, and incorporation of one atom of oxygen
1.14.18	With another compound as one donor, and incorporation of one atom of oxygen
1.14.19	With oxidation of a pair of donors resulting in the reduction of molecular oxygen to two molecules of water
1.14.20	With 2-oxoglutarate as one donor, and the other dehydrogenated
1.14.21	With NADH or NADPH as one donor, and the other dehydrogenated
1.14.99	Miscellaneous (requires further characterization)

1.15. Acting on superoxide as acceptor

1.16. Oxidizing metal ions

1.16.1	With NAD^+ or $NADP^+$ as acceptor
1.16.2	With oxygen as donor

1.17. Acting on -CH$_2$- groups

1.17.1	With NAD^+ or $NADP^+$ as acceptor
1.17.2	With oxygen as acceptor
1.17.4	With a disulfide compound as acceptor
1.17.99	With other acceptors

1.18. Acting on reduced ferredoxin as donor

1.18.1	With NAD^+ or $NADP^+$ as acceptor
1.18.3	With H^+ as acceptor (now EC 1.18.99)
1.18.6	With dinitrogen as acceptor
1.18.96	With other, known, acceptors
1.18.99	With H^+ as acceptor

1.19. Acting on reduced flavodoxin as donor

1.19.6	With dinitrogen as acceptor

Table 6.1. *(Continued)*

  1.20. *Acting on phosphorus or arsenic in donors*
    1.20.1 With NAD(P)$^+$ as acceptor
    1.20.4 With disulfide as acceptor
    1.20.98 With other, known, acceptors
    1.20.99 With other acceptors
  1.21. *Acting on X-H and Y-H to form an X-Y bond*
    1.21.3 With oxygen as acceptor
    1.21.4 With disulfide as acceptor
    1.21.99 With other acceptors
  1.97. *Other oxidoreductases*
2. Transferases
  2.1. *Transferring one-carbon groups*
    2.1.1 Methyltransferases
    2.1.2 Hydroxymethyl-, formyl-, and related transferases
    2.1.3 Carboxyl- and carbamoyl transferases
    2.1.4 Amidinotransferases
  2.2. *Transferring aldehyde or ketonic groups*
    2.2.1 Transketolases and transaldolase
  2.3. *Acyltransferases*
    2.3.1 Transferring groups other than amino-acyl groups
    2.3.2 Aminoacyltransferases
    2.3.3 Acyl groups converted into alkyl on transfer
  2.4. *Glycosyltransferases*
    2.4.1 Hexosyltransferases
    2.4.2 Pentosyltransferases
    2.4.99 Transferring other glycosyl groups
  2.5. *Transferring alkyl or aryl groups, other than methyl groups*
    (There is no subdivision in this section.)
  2.6. *Transferring nitrogenous groups*
    2.6.1 Transaminases
    2.6.2 Amidinotransferases
    2.6.3 Oximinotransferases
    2.6.99 Transferring other nitrogenous groups
  2.7. *Transferring phosphorus-containing groups*
    2.7.1 Phosphotransferases with an alcohol group as acceptor
    2.7.2 Phosphotransferases with a carboxy group as acceptor
    2.7.3 Phosphotransferases with a nitrogenous group as acceptor
    2.7.4 Phosphotransferases with a phosphate group as acceptor
    2.7.6 Diphosphotransferases
    2.7.7 Nucleotidyltransferases
    2.7.8 Transferases for other substituted phosphate groups
    2.7.9 Phosphotransferases with paired acceptors
  2.8. *Transferring sulfur-containing groups*
    2.8.1 Sulfurtransferases
    2.8.2 Sulfotransferases
    2.8.3 CoA-transferases
    2.8.4 Transferring alkylthio groups
  2.9. *Transferring selenium-containing groups*
    2.9.1 Selenotransferases
3. Hydrolases
  3.1. *Acting on ester bonds*
    3.1.1 Carboxylic ester hydrolases
    3.1.2 Phosphoric monoester hydrolases
    3.1.3 Phosphoric diester hydrolases
    3.1.4 Triphosphoric monoester hydrolases
    3.1.5 Sulfuric ester hydrolases

(Continued)

Table 6.1. *(Continued)*

	3.1.6	Diphosphoric monoester hydrolases
	3.1.7	Phosphoric triester hydrolases
	3.1.11	Exodeoxyribonucleases producing 5′-phosphomonoesters
	3.1.13	Exoribonucleases producing 5′-phosphomonoesters
	3.1.14	Exoribonucleases producing 3′-phosphomonoesters
	3.1.15	Exonucleases active with either ribo- or deoxyribonucleic acids and producing 5′-phosphomonoesters
	3.1.16	Exonucleases active with either ribo- or deoxyribonucleic acids and producing 3′-phosphomonoesters
	3.1.21	Endodeoxyribonucleases producing 5′-phosphomonoesters
	3.1.22	Endodeoxyribonucleases producing 3′-phosphomonoesters
	3.1.25	Site-specific endodeoxyribonucleases: specific for altered bases
	3.1.26	Endoribonucleases producing 5′-phosphomonoesters
	3.1.27	Endoribonucleases producing other than 5′-phosphomonoesters
	3.1.30	Endonucleases active with either ribo- or deoxyribonucleic acids and producing 5′-phosphomonoesters
	3.1.31	Endonulceases active with either ribo- or deoxyribonucleic acids and producing 3′-phophomonoesters
3.2.	*Glycosylases*	
	3.2.1	Glycosidases, i.e., enzymes hydrolyzing *O*- and *S*-glycosyl compounds
	3.2.2	Hydrolyzing *N*-glycosyl compounds
	3.2.3	Hydrolyzing *S*-glycosyl compounds
3.3.	*Acting on ether bonds*	
	3.3.1	Trialkylsulfonium hydrolases
	3.3.2	Ether hydrolases
3.4.	*Acting on peptide bonds (peptidases)*	
	3.4.11	Aminopeptidases
	3.4.13	Dipeptidases
	3.4.14	Dipeptidyl-peptidases and tripeptidyl-peptidases
	3.4.15	Peptidyl-dipeptidases
	3.4.16	Serine-type carboxypeptidases
	3.4.17	Metallocarboxypeptidases
	3.4.18	Cysteine-type carboxypeptidases
	3.4.19	Omega peptidases
	3.4.21	Serine endopeptidases
	3.4.22	Cysteine endopeptidases
	3.4.23	Aspartic endopeptidases
	3.4.24	Metalloendopeptidases
	3.4.25	Threonine endopeptidases
	3.4.99	Endopeptidases of unknown catalytic mechanism
3.5.	*Acting on carbon-nitrogen bonds, other than peptide bonds*	
	3.5.1	In linear amides
	3.5.2	In cyclic amides
	3.5.3	In linear amidines
	3.5.4	In cyclic amidines
	3.5.5	In nitriles
	3.5.99	In other compounds
3.6.	*Acting on acid anhydrides*	
	3.6.1	In phosphorus-containing anhydrides
	3.6.2	In sulfonyl-containing anhydrides
	3.6.3	Acting on acid anhydrides; catalyzing transmembrane movement of substances
	3.6.4	Acting on acid anhydrides; involved in cellular and subcellular movements
	3.6.5	Acting on GTP; involved in cellular and subcellular movements
3.7.	*Acting on carbon-carbon bonds*	
	3.7.1	In ketonic substances
3.8.	*Acting on halide bonds*	
	3.8.3	In C-halide compounds

Table 6.1. *(Continued)*

3.9.	*Acting on phosphorus-nitrogen bonds*	
3.10.	*Acting on sulfur-nitrogen bonds*	
3.11.	*Acting on carbon-phosphorus bonds*	
3.12.	*Acting on sulfur-sulfur bonds*	
3.13.	*Acting on carbon-sulfur bonds*	

4. Lyases
- *4.1.* *Carbon-carbon lyases*
  - 4.1.1 Carboxy-lyases
  - 4.1.2 Aldehyde-lyases
  - 4.1.3 Oxo-acid-lyases
  - 4.1.99 Other carbon-carbon lyases
- *4.2.* *Carbon-oxygen lyases*
  - 4.2.1 Hydro-lyases
  - 4.2.2 Acting on polysaccharides
  - 4.2.3 Acting on phosphates
  - 4.2.99 Other carbon-oxygen lyases
- *4.3.* *Carbon-nitrogen lyases*
  - 4.3.1 Ammonia-lyases
  - 4.3.2 Amidine-lyases
  - 4.3.3 Amine-lyases
  - 4.3.99 Other carbon-nitrogen lyases
- *4.4.* *Carbon-sulfur lyases*
- *4.5.* *Carbon-halide lyases*
- *4.6.* *Phosphorus-oxygen lyases*
- *4.99.* *Other lyases*

5. Isomerases
- *5.1.* *Racemases and epimerases*
  - 5.1.1 Acting on amino acids and derivatives
  - 5.1.2 Acting on hydroxy acids and derivatives
  - 5.1.3 Acting on carbohydrates and derivatives
  - 5.1.99 Acting on other compounds
- *5.2.* *Cis-trans-isomerases*
- *5.3.* *Intramolecular oxidoreductases*
  - 5.3.1 Interconverting aldoses and ketoses

*a*Readers should refer to the website: http://www.chem.qmul.ac.uk/iubmb/enzyme/rules.html for the most up-to-date changes.

of the ICUMB (NC-IUBMB). The information is reformatted in table form instead of text form for easier reading and comparison.

Table 6.2 shows the rules for systematic names and guidelines for common names as suggested by NC-IUBMB. Table 6.3 shows the rules and guidelines for particular classes of enzymes as suggested by NC-IUBMB. The concept on reformatting used in Table 6.1 is also applied.

EXAMPLES OF COMMON FOOD ENZYMES

The food industry likes to use terms more easily understood by its people and is slow to adopt changes. For example, some commonly used terms related to enzymes are very general terms and do not follow the recommended guidelines established by NC-IUBMB. Table 6.4 is a list of enzyme groups commonly used by the food industry and researchers (Nagodawithana and Reed 1993).

Table 6.2. General Rules for Generating Systematic Names and Guidelines for Common Names*a*

Rules and Guidelines No.	Descriptions
1.	*Common names*: Generally accepted trivial names of substances may be used in enzyme names. The prefix D-should be omitted for all D-sugars and L-for individual amino acids, unless ambiguity would be caused. In general, it is not necessary to indicate positions of substitutes in common names, unless it is necessary to prevent two different enzymes having the same name. The prefix *keto-* is no longer used for derivatives of sugars in which -CHOH- has been replaced by –CO–; they are named throughout as dehydrosugars.
	Systematic names: To produce usable systematic names, accepted names of substrates forming part of the enzyme names should be used. Where no accepted and convenient trivial names exist, the official IUPAC rules of nomenclature should be applied to the substrate name. The 1, 2, 3 system of locating substitutes should be used instead of the α β γ system, although group names such as β-aspartyl-, γ-glutamyl- and also β-alanine-lactone are permissible; α and β should normally be used for indicating configuration, as in α-D-glucose. For nucleotide groups, adenylyl (not adenyl), etc. should be the form used. The name oxo acids (not keto acids) may be used as a class name, and for individual compounds in which –CH2– has been replaced by –CO–, oxo should be used.
2.	Where the substrate is normally in the form of an anion, its name should end in *-ate* rather than *-ic,* e.g., *lactate dehydrogenase*, not "lactic acid dehydrogenase."
3.	Commonly used abbreviations for substrates, e.g., ATP, may be used in names of enzymes, but the use of new abbreviations (not listed in recommendations of the IUPAC-IUB Commission on Biochemical Nomenclature) should be discouraged. Chemical formulae should not normally be used instead of names of substrates. Abbreviations for names of enzymes, e.g., GDH, should not be used.
4.	Names of substrates composed of two nouns, such as glucose phosphate, which are normally written with a space, should be hyphenated when they form part of the enzyme names, and thus become adjectives, e.g., *glucose-6-phosphate dehydrogenase* (EC 1.1.1.49). This follows standard practice in phrases where two nouns qualify a third; see e.g., *Handbook of Chemical Society Authors*, 2nd ed., p. 14 (The Chemical Society, London, 1961).

Table 6.2. *(Continued)*

Rules and Guidelines No.	Descriptions
5.	The use as enzyme names of descriptions such as *condensing enzyme, acetate-activating enzyme,* and *pH 5 enzyme* should be discontinued as soon as the catalyzed reaction is known. The word *activating* should not be used in the sense of converting the substrate into a substance that reacts further; all enzymes act by activating their substrates, and the use of the word in this sense may lead to confusion.
6.	*Common names*: If it can be avoided, a common name should not be based on a substance that is not a true substrate, e.g., enzyme EC 4.2.1.17 *(Enoyl-CoA hydratase)* should not be called "crotonase," since it does not act on crotonate.
7.	*Common names*: Where a name in common use gives some indication of the reaction and is not incorrect or ambiguous, its continued use is recommended. In other cases, a common name is based on the same principles as the systematic name (see later), but with a minimum of detail, to produce a name short enough for convenient use. A few names of proteolytic enzymes ending in *-in* are retained; all other enzyme names should end in *-ase*.
	Systematic names: Systematic names consist of two parts. The first contains the name of the substrate or, in the case of a bimolecular reaction, of the two substrates separated by a colon. The second part, ending in *-ase*, indicates the nature of the reaction.
8.	A number of generic words indicating a type of reaction may be used in either common or systematic names: *oxidoreductase, oxygenase, transferase* (with a prefix indicating the nature of the group transferred), *hydrolase, lyase, racemase, epimerase, isomerase, mutase, ligase.*
9.	*Common names*: A number of additional generic names indicating reaction types are used in common names, but not in the systematic nomenclature, e.g., *dehydrogenase, reductase, oxidase, peroxidase, kinase, tautomerase, dehydratase,* etc.
10.	Where additional information is needed to make the reaction clear, a phrase indicating the reaction or a product should be added in parentheses after the second part of the name, e.g., *(ADP-forming), (dimerizing), (CoA-acylating).*
11.	*Common names*: The direct attachment of *-ase* to the name of the substrate will indicate that the enzyme brings about hydrolysis.
	Systematic names: The suffix *-ase* should never be attached to the name of the substrate.
12.	*Common names*: The name "dehydrase," which was at one time used for both dehydrogenating and dehydrating enzymes, should not be used. *Dehydrogenase* will be used for the former and *dehydratase* for the latter.
13.	*Common names*: Where possible, common names should normally be based on a reaction direction that has been demonstrated, e.g., *dehydrogenase* or *reductase, decarboxylase* or *carboxylase.*
	Systematic names: In the case of reversible reactions, the direction chosen for naming should be the same for all the enzymes in a given class, even if this direction has not been demonstrated for all. Thus, systematic names may be based on a written reaction, even though only the reverse of this has been actually demonstrated experimentally.
14.	*Systematic names*: When the overall reaction included two different changes, e.g., an oxidative demethylation, the classification and systematic name should be based, whenever possible, on the one (or the first one) catalyzed by the enzyme: the other function(s) should be indicated by adding a suitable participle in parentheses, as in the case of *sarcosine:oxygen oxidoreductase (demethylating)* (EC 1.5.3.1); D-*aspartate:oxygen oxidoreductase (deaminating)* (EC 1.4.3.1); L-*serine hydro-lyase (adding indole glycerol-phosphatase)* (EC 4.2.1.20).
15.	When an enzyme catalyzes more than one type of reaction, the name should normally refer to one reaction only. Each case must be considered on its merits, and the choice must be, to some extent, arbitrary. Other important activities of the enzyme may be indicated in the list under "reaction" or "comments."
	Similarly, when any enzyme acts on more than one substrate (or pair of substrates), the name should normally refer only to one substrate (or pair of substrates), although in certain cases it may be possible to use a term that covers a whole group of substrates, or an alternative substrate may be given in parentheses.
16.	A group of enzymes with closely similar specificities should normally be described by a single entry. However, when the specificity of two enzymes catalyzing the same reactions is sufficiently different (the degree of difference being a matter of arbitrary choice) two separate entries may be made, e.g., EC 1.2.1.4 (Aldehyde dehydrogenase (NADP$^+$)) and EC 1.2.1.7 (Benzylaldehyde (NADP$^+$)).

Table 6.3. Rules and Guidelines for Particular Classes of Enzymes[a]

Rules and Guidelines No.	Description
Class 1: Oxidoreductases	
1.	*Common names*: The terms *dehydrogenase* or *reductase* will be used much as hitherto. The latter term is appropriate when hydrogen transfer from the substance mentioned as donor in the systematic name is not readily demonstrated. *Transhydrogenase* may be retained for a few well-established cases. *Oxidase* is used only for cases where O_2 acts as an acceptor, and *oxygenase* only for those cases where the O_2 molecule (or part of it) is directly incorporated into the substrate. *Peroxidase* is used for enzymes using H_2O_2 as acceptor. *Catalase* must be regarded as exceptional. Where no ambiguity is caused, the second reactant is not usually named; but where required to prevent ambiguity, it may be given in parentheses, e.g., EC 1.1.1.1, *alcohol dehydrogenase* and EC 1.1.1.2 *alcohol dehydrogenase (NADP$^+$)*. Systematic names: All enzymes catalyzing oxidoreductions should be *oxidoreductases* in the systematic nomenclature, and the names formed on the pattern *donor:acceptor oxidoreductase*.
2.	*Systematic names*: For oxidoreductases using NAD^+ or $NADP^+$, the coenzyme should always be named as the acceptor except for the special case of Section 1.6 (enzymes whose normal physiological function is regarded as reoxidation of the reduced coenzyme). Where the enzyme can use either coenzyme, this should be indicated by writing $NAD(P)^+$.
3.	Where the true acceptor is unknown and the oxidoreductase has only been shown to react with artificial acceptors, the word *acceptor* should be written in parentheses, as in the case of EC 1.3.99.1, *succinate:(acceptor)oxidoreductase*.
4.	*Common names*: Oxidoreductases that bring about the incorporation of molecular oxygen into one donor or into either or both of a pair of donors are named *oxygenase*. If only one atom of oxygen is incorporated, the term *monooxygenase* is used; if both atoms of O_2 are incorporated, the term *dioxygenase* is used. *Systematic names*: Oxidoreductases that bring about the incorporation of oxygen into one pair of donors should be named on the pattern *donor, donor:oxygen oxidoreductase (hydroxylating)*.
Class 2: Transferases	
1.	*Common names*: Only one specific substrate or reaction product is generally indicated in the common names, together with the group donated or accepted. The forms *transaminase,* etc. may be used, if desired, instead of the corresponding forms *aminotransferase,* etc. A number of special words are used to indicate reaction types, e.g., *kinase* to indicate a phosphate transfer from ATP to the named substrate (not "phosphokinase"), *diphospho-kinase* for a similar transfer of diphosphate. *Systematic names*: Enzymes catalyzing group-transfer reactions should be named *transferase,* and the names formed on the pattern *donor:acceptor group-transferred-transferase,* e.g., *ATP:acetate phosphotransferase* (EC 2.7.2.1). A figure may be prefixed to show the position to which the group is transferred, e.g., *ATP:D-fructose 1-phospho-transferase* (EC 2.7.1.3). The spelling "transphorase" should not be used. In the case of the phosphotransferases, ATP should always be named as the donor. In the case of the transaminases involving 2-oxoglutarate, the latter should always be named as the acceptor.
2.	*Systematic names*: The prefix denoting the group transferred should, as far as possible, be noncommittal with respect to the mechanism of the transfer, e.g., *phospho-* rather than *phosphate-*.
Class 3. Hydrolases	
1.	*Common names*: The direct addition of *-ase* to the name of the substrate generally denotes a hydrolase. Where this is difficult, e.g., EC 3.1.2.1 (acetyl-CoA hydrolase), the word *hydrolase* may be used. Enzymes should not normally be given separate names merely on the basis of optimal conditions for activity. The *acid and alkaline phosphatases* (EC 3.1.3.1–2) should be regarded as special cases and not as examples to be followed. The common name *lysozyme* is also exceptional. *Systematic names*: Hydrolyzing enzymes should be systematically named on the pattern *substrate hydrolase*. Where the enzyme is specific for the removal of a particular group, the group may be named as a prefix, e.g., *adenosine aminohydrolase* (EC 3.5.4.4). In a number of cases, this group can also be transferred by the enzyme to other molecules, and the hydrolysis itself might be regarded as a transfer of the group to water.
Class 4. Lyases	
1.	*Common names*: The names *decarboxylase, aldolase,* etc. are retained; and *dehydratase* (not "dehydrase") is used for the hydro-lyases. "Synthetase" should not be used for any enzymes in this class. The term *synthase* may be used instead for any enzyme in this class (or any other class) when it is desired to emphasize the synthetic aspect of the reaction.

Table 6.3. *(Continued)*

Rules and Guidelines No.	Description
	Systematic names: Enzymes removing groups from substrates nonhydrolytically, leaving double bonds (or adding groups to double bonds) should be called *lyases* in the systematic nomenclature. Prefixes such as *hydro-, ammonia-* should be used to denote the type of reaction, e.g., (*S*)-*malate hydro-lyase* (EC 4.2.1.2). Decarboxylases should be regarded as *carboxy-lyases*. A hyphen should always be written before *lyase* to avoid confusion with hydrolases, carboxylases, etc.
2.	*Common names*: Where the equilibrium warrants it, or where the enzyme has long been named after a particular substrate, the reverse reaction may be taken as the basis of the name, using *hydratase, carboxylase,* etc., e.g., *fumarate hydratase* for EC 4.2.1.2 (in preference to "fumarase,"which suggests an enzyme hydrolyzing fumarate).
	Systematic names: The complete molecule, not either of the parts into which it is separated, should be named as the substrate. The part indicated as a prefix to *-lyase* is the more characteristic and usually, but not always, the smaller of the two reaction products. This may either be the removed (saturated) fragment of the substrate molecule, as in *ammonia-, hydro-, thiol-lyase,* or the remaining unsaturated fragment, e.g., in the case of *carboxy-, aldehyde- or oxo-acid-lyases*.
3.	Various subclasses of the lyases include a number of strictly specific or group-specific pyridoxal-5-phosphate enzymes that catalyze *elimination* reactions of β- or γ-substituted α-amino acids. Some closely related pyridoxal-5-phosphate-containing enzymes, e.g., *tryptophan synthase* (EC 4.2.1.20) and *cystathionine-synthase* (4.2.1.22) catalyze *replacement* reactions in which a β-, or γ-substituent is replaced by a second reactant without creating a double bond. Formally, these enzymes appeared to be transferases rather than lyases. However, there is evidence that in these cases the elimination of the β- or γ-substituent and the formation of an unsaturated intermediate is the first step in the reaction. Thus, applying rule 14 of the general rules for systematic names and guidelines for common names (Table 6.2), these enzymes are correctly classified lyases.
Class 5. Isomerases	
In this class, the common names are, in general, similar to the systematic names that indicate the basis of classification.	
1.	*Isomerase* will be used as a general name for enzymes in this class. The types of isomerization will be indicated in systematic names by prefixes, e.g., *maleate cis-trans-isomerase* (EC 5.2.1.1), *phenylpyruvate keto-enol-isomerase* (EC 5.3.2.1), *3-oxosteroid* Δ^5-Δ^4-isomerase (EC 5.3.3.1). Enzymes catalyzing an aldose-ketose interconversion will be known as *ketol-isomerases,* e.g., L-*arabinose ketol-isomerase* (EC 5.3.1.4). When the isomerization consists of an intramolecular transfer of a group, the enzyme is named a *mutase,* e.g., EC 5.4.1.1 (lysolecithin acylmutase) and the *phosphomutases* in sub-subclass 5.4.2 (Phosphotransferases); when it consists of an intramolecular lyase-type reaction, e.g., EC 5.5.1.1 (muconate cycloisomerase), it is systematically named a *lyase (decyclizing)*.
2.	Isomerases catalyzing inversions at asymmetric centers should be termed *racemases* or *epimerases,* according to whether the substrate contains one, or more than one, center of asymmetry: compare, e.g., EC 5.1.1.5 (lysine racemase) with EC 5.1.1.7 (diaminopimelate epimerase). A numerical prefix to the word *epimerase* should be used to show the position of the inversion.
Class 6. Ligases	
1.	*Common names*: Common names for enzymes of this class were previously of the type *XP synthetase.* However, as this use has not always been understood, and synthetase has been confused with synthase (see Class 4, item 1), it is now recommended that as far as possible the common names should be similar in form to the systematic name.
	Systematic names: The class of enzymes catalyzing the linking together of two molecules, coupled with the breaking of a diphosphate link in ATP, etc. should be known as *ligases*. These enzymes were often previously known as "synthetase"; however, this terminology differs from all other systematic enzyme names in that it is based on the product and not on the substrate. For these reasons, a new systematic class name was necessary.
2.	*Common name*: The common names should be formed on the pattern *X-Y ligase,* where X-Y is the substance formed by linking X and Y. In certain cases, where a trivial name is commonly used for XY, a name of the type *XY synthase* may be recommended (e.g*.,* EC 6.3.2.11, *carnosine synthase*).
	Systematic names: The systematic names should be formed on the pattern *X:Y ligase (ADP-forming)*, where X and Y are the two molecules to be joined together. The phrase shown in parentheses indicates both that ATP is the triphosphate involved and that the terminal diphosphate link is broken. Thus, the reaction is X + Y + ATP = X–Y + ADP + P_i.
3.	*Common name*: In the special case where glutamine acts an ammonia donor, this is indicated by adding in parentheses (*glutamine-hydrolyzing*) to a ligase name.
	Systematic names: In this case, the name *amido-ligase* should be used in the systematic nomenclature.

Table 6.4. Common Enzyme Group Terms Used in the Food Industry

Group Term	Selected Enzymes in This Group
Carbohydrases	Amylases (EC 3.2.1.1, 3.2.1.2, 3.2.1.3)
	Pectic enzymes (see later)
	Lactases (EC 3.2.1.108, 3.2.1.23)
	Invertase (EC 3.2.1.26)
	α-galactosidases (EC 3.2.1.22, 3.2.1.23)
	Cellulase (EC 3.2.1.4)
	Hemicellulases (EC not known)
	Dextranase (EC 3.2.1.11)
Proteases	Serine proteases (EC 3.4.21)
(Endopeptidases)	Cysteine proteases (EC 3.4.22)
	Aspartic proteases (EC 3.4.23)
	Metalloproteases (EC 3.4.24)
Proteases	Aminopeptidases (EC 3.4.11)
(Exopeptidase)	
Proteases	Carboxypeptidases (EC 3.4.16)
(Carboxypeptidases)	Metallocarboxypeptidases (EC 3.4.17)
	Cysteine carboxypeptidases (EC 3.4.18)
	Dipeptide hydrolases (EC 3.4.13)
Oxidoreductases	Polyphenol oxidase (EC 1.10.3.1)
	Peroxidase (EC 1.11.1.7)
	Lactoperoxidase (EC 1.11.1.7)
	Catalase (EC 1.11.1.6)
	Sulfhydryl oxidase (EC 1.8.3.2)
	Glucose oxidase (EC 1.1.3.4)
	Pyranose oxidase (EC 1.1.3.10)
	Xanthine oxidase (EC 1.1.3.22)
	Lipoxygenase (EC 1.13.11.12)
	Dehydrogenases (see below)
	Alcohol oxidase (EC 1.1.3.13)
Pectolytic enzymes	Pectin (methyl) esterase (PE, EC 3.1.11.1)
(Pectic enzymes)	Polygalacturonase (PG, EC 3.2.2.15 or 3.2.1.67)
	Pectate lyases or pectic acid lyases (PAL)
	(Endo-type, EC 3.2.1.15 or 4.2.2.2)
	(Exo-type, EC 3.2.1.67 or 4.2.2.9)
	Pectic lyase (PL, EC 4.2.2.10)
Heme enzymes	Catalase (EC 1.11.1.6)
	Peroxidase (EC 1.11.1.7)
	Phenol oxidase (Monophenol monooxygenase, EC 1.14.18.1 ?)
	Lipoperoxidase (EC 1.13.11.12)
Hemicellulase	Glucanases (EC 3.2.1.6, 3.2.1.39, 3.2.1.58, 3.2.1.75, 3.2.1.59, 3.2.1.71, 3.2.1.74, 3.2.1.84)
	Xylanase (EC 3.2.1.32)
	Galactanases (EC 3.2.1.89, 3.2.1.23, 3.2.1.145)
	Mannanase (EC 3.2.1.25)
	Galactomannanases (EC not known)
	Pentosanases (EC not known)
Nucleolytic enzymes	Nucleases
	(Endonucleases, EC 3.1.30 or 3.1.27)
	(Exonucleases, EC 3.1.15 or 3.1.14)
	Phosphatases
	(Nonspecific phosphatases, EC 3.1.3)
	(Nucleotidases, EC 3.1.3)
	Nucleosidases (EC 3)
	(Inosinate nucleosidase, EC 3.2.2.12)
	Nucleodeaminases
	(Adenine deaminase, EC 3.5.4.2)
Dehydrogenase	Alcohol dehydrogenase (EC 1.1.1.1)
	Shikimate dehydrogenase (EC 1.1.1.25)
	Maltose dehydrogenase (EC 3.1 to 3.3)
	Isocitrate dehydrogenase (EC 1.1.1.41, 1.1.1.42)
	Lactate dehydrogenase (EC 1.1.1.3, 1.1.1.4, 1.1.1.27)

Table 6.5. Recommended Names, Systematic Names, and Enzyme Codes (EC) for Some Common Food Enzymes

Recommended Name	Systematic Name	Enzyme Code (EC)
5′-nulceotidase	5′-ribonucleotide phosphohydrolase	3.1.3.5
α-amylase (Glycogenase)	1,4-α-D-glucan glucanohydrolase	3.2.1.1
α-galactosidase (Melibiase)	α-D-galactoside galactohydrolase	3.2.1.22
α-glucosidase (Maltase, glucoinvertase, glucosidosucrase, maltase-glucoamylase)	α-D-glucoside glucohydrolase	3.2.1.20
D-amino acid oxidase	D-amino-acid:oxygen oxidoreductase (deaminating)	1.4.3.3
D-lactate dehydrogenase (Lactic acid dehydrogenase)	(R)-lactate:NAD(+) oxidoreductase	1.1.1.28
L-amino acid oxidase	L-amino-acid:oxygen oxidoreductase (deaminating)	1.4.3.2
L-lactate dehydrogenase (Lactic acid dehydrogenase)	(S)-lactate:NAD(+) oxidoreductase	1.1.1.27
β-amylase (Saccharogen amylase, glycogenase)	1,4-α-D-glucan maltohydrolase	3.2.1.2
β-galactosidase (Lactase)	β-D-galactoside galactohydrolase	3.2.1.23
β-glucosidase (Gentiobiase, cellobiase, amyygdalase)	β-D-glucoside glucohydrolase	3.2.1.21
β-glucanase, see Hemicellulase		
Acid phosphatase (Acid phosphomonoesterase, phosphomonoesterase, glycerol phosphatase)	Orthophosphoric-monoester phosphohydrolase (acid optimum)	3.1.3.2
Adenine deaminase (Adenase, adenine aminase)	Adenine aminohydrolase	3.5.4.2
Adenosine phosphate deaminase	Adenosine-phosphate aminohydrolase	3.5.4.17
AMP deaminase (Adenylic acid deaminase, AMP aminase)	AMP aminohydrolase	3.5.4.6
Alcalase, see Subtilisin Carlsberg		
Alcohol dehydrogenase (Aldehyde reductase)	Alcohol:NAD(+) oxidoreductase	1.1.1.1
Alcohol oxidase	Alcohol:oxygen oxidoreductase	1.1.3.13
Alkaline phosphatase (Alkaline phosphomono-esterase, phosphomonoesterase, glycerolphosphatase)	Orthophosphoric-monoester phosphohydrolase(alkaline optimum)	3.1.3.1
Alliin lyase (Alliinase)	Alliin alkyl-sulfenate-lyase	4.4.1.4
Aminoacylase (Dehydropeptidase II, histozyme, acylase I, hippuricase, benzamidase)	*N-acyl-L-amino-acid amidohydrolase*	3.5.1.14
Aspartate amino-lyase (fumaric aminase)	L-amino-acid:oxygen oxidoreductase (deaminating)	4.3.1.1
Aspergillus nuclease S (1) [Endonuclease S (1) (aspergillus), single-stranded-nucleate endo-nuclease, deoxyribonuclease S (1)]	None, see comments in original reference	3.1.30.1
Bacillus thermoproteolyticus neutral proteinase (Thermolysin)	None, see comments in original reference	3.4.24.4
Bromelain	None, see comments in original reference	3.4.22.4

(Continued)

Table 6.5. *(Continued)*

Recommended Name	Systematic Name	Enzyme Code (EC)
Carboxy peptidase α (Carboxypolypeptidase)	Peptidyl-L-amino-acid hydrolase	3.4.17.1
Catalase	Hydrogen-peroxide:hydrogen-peroxide oxidoreductase	1.11.1.6
Catechol oxidase (Diphenol oxidase, o-diphenolase, phenolase, polyphenol oxidase, tyrosinase)	1,2-benzenediol:oxygen oxidoreductase	1.10.3.1
Cellulase (Endo-1,4-β-glucanase)	1,4-(1,3:1,4)-β-D-glucan 4-glucanohydrolase	3.2.1.4
Chymosin (Rennin)	None, see comments in original reference	3.4.23.4
Chymotrypsin (Chymotrypsin α and β)	None, see comments in original reference	3.4.21.1
Debranching enzyme, see α-dextrin endo-1,6-α-glucosidase		
Dextranase	1,6-α-D-glucan 6-glucanohydrolase	3.2.1.11
α-dextrin endo-1,6-α-glucosidase (Limit dextrinase, debranching enzyme, amylopectin 6-gluco-hydrolase, pullulanase)	α-dextrin 6-glucanohydrolase	3.2.1.41
Diastase (obsolete term)		3.2.1.1 (obsolete)
Dipeptidase	Dipeptide hydrolase	3.4.13.11
Dipeptidyl peptidase I (Cathepsin C, dipeptidyl-amino-peptidase I, dipeptidyl transferase)	Dipeptidyl-peptide hydrolase	
Endopectate lyase, see Pectate lyase		
Exoribonuclease II (Ribonuclease II)	None, see comments in original reference	3.1.13.1
Exoribonuclease H	None, see comments in original reference	3.1.13.2
Ficin	None, see comments in original reference	3.4.22.3
Galactose oxidase	D-galactose-1,4-lactone:oxygen 2-oxidoreductase	1.1.3.9
Glucan-1,4-α-glucosidase (Glucoamylase, amyloglucosidase, γ-amylase, acid maltase, lysosomal α-glucosidase, exo-1,4-α-glucosidase)	1,4-α-D-glucan glucohydrolase	3.2.1.3
Glucose-6-phosphate isomerase [Phosphohexose isomerase, phosphohexomutase, oxoisomerase, hexosephosphate isomerase phosphosaccharomutase, phosphoglucoisomerase, phosphohexoisomerase, glucose isomerase (deleted, obsolete)]	D-glucose-6-phosphate keto-isomerase	5.3.1.9
Glucokinase	ATP:D-gluconate 6-phosphotransferase	2.7.1.12
Glucose oxidase (Glucose oxyhydrase)	β-D-glucose:oxygen 1-oxidoreductase	1.1.3.4
Glycerol kinase	ATP:glycerol 3-phosphotransferase	2.7.1.30
Glycogen (starch) synthase (UDPglucose-glycogen glucosyl-transferase)	UDPglucoase:glycogen glucosyltransferase	2.4.1.11
Inosinate nucleosidase (Inosinase)	5′-inosinate phosphoribohydrolase	3.2.2.2
β-fructofuranosidase (invertase, saccharase)	β-D-fructofuranoside fructohydrolase	3.2.1.26
Lactase	Lactose galactohydrolase	3.2.1.108
D-lactate dehydrogenase (Lactic acid dehydrogenase)	(R)-lactate:NAD(+) oxidoreductase	1.1.1.28

Table 6.5. *(Continued)*

Recommended Name	Systematic Name	Enzyme Code (EC)
L-lactate dehydrogenase (Lactic acid dehydrogenase)	(*S*)-lactate:NAD(+) oxidoreductase	1.1.1.27
Lipoxygenase (Lipoxidase, carotene oxidase)	Linoleate:oxygen oxidoreductase	1.13.11.12
Lysozyme (Muramidase)	Peptidoglycan N-acetylmuramoylhydrolase	3.2.1.17
Malate dehydrogenase (Malic dehydrogenase)	(S)-malate:NAD(+) oxidoreductase	1.1.1.37
Microbial aspartic proteinase (Trypsinogen kinase)	None, see comments in original reference	3.4.23.6
Monophenol monooxygenase (Tyrosinase, phenalase, monophenol oxidase, cresolase)	Monophenol, L-dopa:oxygen oxidoreductase	1.14.18.1
Palmitoyl-CoA hydrolase (Long-chain fatty-acyl-CoA hydrolase)	Palmitoyl-CoA hydrolase	3.1.2.2
Papain (Papaya peptidase I)	None, see comments in original reference	3.4.22.2
Pectate lyase (Pectate transliminase)	Poly (1,4-α-D-galacturonide) lyase	4.2.2.2
Pectic esterase (Pectin demethoxylase, pectin methoxylase, pectin methylesterase)	Pectin pectylhydrolase	3.1.1.11
Pepsin A (Pepsin)	None, see comments in original reference	3.4.23.1
Peroxidase	Donor:hydrogen-peroxide oxidoreductase	1.11.1.7
Phosphodiesterase I (5′-exonuclease)	Oligonucleate 5'-nucleotidohydrolase	3.1.4.1
Phosphoglucomutase (Glucose phosphomutase)	α-D-glucose 1,6-phosphomutase	5.4.2.2
Phosphorylase (Muscle phosphorylase α and β, amylophosphorylase, polyphosphorylase)	1,4-α-D-glucan:orthophosphate α-D-glucosyltransferase	2.4.1.1
Plasmin (Fibrinase, fibrinolysin)	None, see comments in original reference	3.4.21.7
Polygalacturonase (Pectin depolymerase, pectinase)	Poly (1,4-α-D-galacturonide) glycanohydrolase	3.2.1.15

Table 6.5 lists some common names, systematic names, and EC numbers for some common food enzymes.

Enzyme classification and nomenclature are now standardized procedures. Some journals already require that enzyme codes be used in citing or naming enzymes. Other journals are following the trend. It is expected that all enzymes will have enzyme codes in new research articles as well as (one hopes) in new reference books. However, for older literature, it is still difficult to identify the enzyme codes. It is hoped that Tables 6.4 and 6.5 will be useful as references.

Biocatalysis, Enzyme Engineering and Biotechnology

G. A. Kotzia, D. Platis, I. A. Axarli, E. G. Chronopoulou, C. Karamitros, and N. E. Labrou

Abstract: Enzymes are biocatalysts evolved in nature to achieve the speed and coordination of nearly all the chemical reactions that define cellular metabolism necessary to develop and maintain life. The application of biocatalysis is growing rapidly, since enzymes offer potential for many exciting applications in industry. The advent of whole genome sequencing projects enabled new approaches for biocatalyst development, based on specialised methods for enzyme heterologous expression and engineering. The engineering of enzymes with altered activity, specificity and stability, using site-directed mutagenesis and directed evolution techniques are now well established. Over the last decade, enzyme immobilisation has become important in industry. New methods and techniques for enzyme immobilisation allow for the reuse of the catalysts and the development of efficient biotechnological processes. This chapter reviews advances in enzyme technology as well as in the techniques and strategies used for enzyme production, engineering and immobilisation and discuss their advantages and disadvantages.

PREFACE

Enzymes are proteins with powerful catalytic functions. They increase reaction rates sometimes by as much as one million fold, but more typically by about one thousand fold. Catalytic activity can also be shown, to a limited extent, by biological molecules other than the 'classical' enzymes. For example, antibodies raised to stable analogues of the transition states of a number of enzyme-catalysed reactions can act as effective

catalysts for those reactions (Hsieh-Wilson et al. 1996). In addition, RNA molecules can also act as a catalyst for a number of different types of reactions (Lewin 1982). These antibodies and RNA catalysts are known as abzymes and ribozymes, respectively.

Enzymes have a number of distinct advantages over conventional chemical catalysts. Among these are their high productivity, catalytic efficiency, specificity and their ability to discriminate between similar parts of molecules (regiospecificity) or optical isomers (stereospecificity). Enzymes, in general, work under mild conditions of temperature, pressure and pH. This advantage decreases the energy requirements and therefore reduces the capital costs. However, there are some disadvantages in the use of enzymes, such as high cost and low stability. These shortcomings are currently being addressed mainly by employing protein engineering approaches using recombinant DNA technology (Stemmer 1994, Ke and Madison 1997). These approaches aim at improving various properties such as thermostability, specificity and catalytic efficiency. The advent of designer biocatalysts enables production of not only process-compatible enzymes, but also novel enzymes able to catalyse new or unexploited reactions (Schmidt-Dannert et al. 2000, Umeno and Arnold 2004). This is just the start of the enzyme technology era.

## ENZYME STRUCTURE AND MECHANISM

NOMENCLATURE AND CLASSIFICATION OF ENZYMES

Enzymes are classified according to the nature of the reaction they catalyse (e.g. oxidation/reduction, hydrolysis, synthesis, etc.) and sub-classified according to the exact identity of their substrates and products. This nomenclature system was established by the *Enzyme Commission* (a committee of the International Union of Biochemistry). According to this system, all enzymes are classified into six major classes:

1. *Oxidoreductases*, which catalyse oxidation–reduction reactions.
2. *Transferases*, which catalyse group transfer from one molecule to another.
3. *Hydrolases*, which catalyse hydrolytic cleavage of C–C, C–N, C–O, C–S or O–P bonds. These are group transfer reactions but the acceptor is always water.
4. *Lyases*, which catalyse elimination reactions, resulting in the cleavage of C–C, C–O, C–N, C–S bonds or the formation of a double bond, or conversely adding groups to double bonds.
5. *Isomerases*, which catalyse isomerisation reactions, e.g., racemisation, epimerisation, *cis-trans*-isomerisation, tautomerisation.
6. *Ligases*, which catalyse bond formation, coupled with the hydrolysis of a high-energy phosphate bond in ATP or a similar triphosphate.

The Enzyme Commission system consists of a numerical classification hierarchy of the form 'E.C. a.b.c.d' in which 'a' represents the class of reaction catalysed and can take values from 1 to 6 according to the classification of reaction types given above. 'b' denotes the sub-class, which usually specifies more precisely the type of the substrate or the bond cleaved, e.g. by naming the electron donor of an oxidation–reduction reaction or by naming the functional group cleaved by a hydrolytic enzyme. 'c' denotes the sub-subclass, which allows an even more precise definition of the reaction catalysed. For example, sub-subclasses of oxidoreductases are denoted by naming the acceptor of the electron from its respective donor. 'd' is the serial number of the enzyme within its sub-subclass. An example will be analysed. The enzyme that oxidises D-glucose using molecular oxygen catalyses the following reaction:

β-D-Glucose   D-Glucono-1,5-lactone
Scheme 7.1.

Hence, its systematic name is D-glucose: oxygen oxidoreductase, and its systematic number is EC 1.1.3.4.

The systematic names are often quite long, and therefore, short trivial names along with systematic numbers are often more convenient for enzyme designation. These shorter names are known as *recommended names*. The recommended names consist of the suffix '–ase' added to the substrate acted on. For example for the enzyme mentioned above, the recommended name is glucose oxidase.

It should be noted that the system of nomenclature and classification of enzymes is based only on the reaction catalysed and takes no account of the origin of the enzyme, that is from the species or tissue it derives.

BASIC ELEMENTS OF ENZYME STRUCTURE

The Primary Structure of Enzyme

Enzymes are composed of L-α-amino acids joined together by a *peptide bond* between the carboxylic acid group of one amino acid and the amino group of the next.

Peptitde bond
Scheme 7.2.

There are 20 common amino acids in proteins, which are specified by the genetic code; in rare cases, others occur as the products of enzymatic modifications after translation. A common

feature of all 20 amino acids is a central carbon atom (C_α) to which a hydrogen atom, an amino group (–NH$_2$) and a carboxy group (–COOH) are attached. Free amino acids are usually zwitterionic at neutral pH, with the carboxyl group deprotonated and the amino group protonated. The structure of the most common amino acids found in proteins is shown in Table 7.1. Amino acids can be divided into four different classes depending on the structure of their side chains, which are called R groups: non-polar, polar uncharged, negatively charged (at neutral pH) and positively charged (at neutral pH; Richardson 1981). The properties of the amino acid side chains determine the properties of the proteins they constitute. The formation of a succession of peptide bonds generates the 'main chain' or 'backbone'.

The primary structure of a protein places several constrains on how it can fold to produce its three-dimensional structure (Cantor 1980, Fersht 1999). The backbone of a protein consists of a carbon atom C_α to which the side chain is attached, a NH group bound to C_α and a carbonyl group C = O, where the carbon atom C is attached to C_α (Fig. 7.1) The peptide bond is planar since it has partial (∼40%) double bond character with π electrons shared between the C–O and C–N bonds (Fig. 7.1). The peptide bond has a *trans*-conformation, that is the oxygen of the carbonyl group and the hydrogen of the NH group are in the *trans* position; the *cis* conformation occurs only in exceptional cases (Richardson 1981).

Enzymes have several 'levels' of structure. The protein's sequence, that is the order of amino acids, is termed as its 'primary structure'. This is determined by the sequence of nucleotide bases in the gene that codes for the protein. Translation of the mRNA transcript produces a linear chain of amino acids linked together by a peptide bond between the carboxyl carbon of the

first amino acid and the free amino group of the second amino acid. The first amino acid in any polypeptide sequence has a free amino group and the terminal amino acid has a free carboxyl group. The primary structure is responsible for the higher levels of enzyme's structure and therefore for the enzymatic activity (Richardson 1981, Price and Stevens 1999).

The Three-Dimensional Structure of Enzymes

Enzymes are generally very closely packed globular structures with only a small number of internal cavities, which are normally filled by water molecules. The polypeptide chains of enzymes are organised into ordered, hydrogen bonded regions, known as *secondary structure* (Andersen and Rost 2003). In these ordered structures, any buried carbonyl oxygen forms a hydrogen bond with an amino NH group. This is done by forming α-helices and β-pleated sheets, as shown in Figure 7.2. The α-helix can be thought of as having a structure similar to a coil or spring (Surewicz and Mantsch 1988). The β-sheet can be visualised as a series of parallel strings laid on top of an accordion-folded piece of paper. These structures are determined by the protein's primary structure. Relatively small, uncharged, polar amino acids readily organise themselves into α-helices, while relatively small, non-polar amino acids form β-sheets. Proline is a special amino acid because of its unique structure (Table 7.1). Introduction of proline into the sequence creates a permanent bend at that position (Garnier et al. 1990). Therefore, the presence of proline in an α-helix or β-sheet disrupts the secondary structure at that point. The presence of a glycine residue confers greater than normal flexibility on a polypeptide chain. This is due to the absence of a bulky side chain, which reduces steric hindrance.

Another frequently observed structural unit is the β-turn (Fang and Shortle 2003). This occurs when the main chain sharply changes direction using a bend composed of four successive residues, often including proline and glycine. In these units, the C = O group of residue i is hydrogen bonded to the NH of residue i+3 instead of i+4 as in α-helix. Many different types of β-turn have been identified, which differ in terms of the number of amino acids and in conformation (e.g. Type I, Type II, Type III; Sibanda et al. 1989).

The three-dimensional structure of a protein composed of a single polypeptide chain is known as its *tertiary structure*. Tertiary structure is determined largely by the interaction of R groups on the surface of the protein with water and with other R groups on the protein's surface. The intermolecular non-covalent attractive forces that are involved in stabilising the enzyme's structure are usually classified into three types: ionic bonds, hydrogen bonds and van der Waals attractions (Matthews 1993). Hydrogen bonding results from the formation of hydrogen bridges between appropriate atoms; electrostatic bonds are due to the attraction of oppositely charged groups located on two amino acid side chains. Van der Waals bonds are generated by the interaction between electron clouds. Another important weak force is created by the three-dimensional structure of water, which tends to force hydrophobic groups together in order to minimise their disruptive effect on hydrogen-bonded

Figure 7.2. Representation of α-helix and β-sheet. Hydrogen bonds are depicted by doted lines.

network of water molecules. Apart from the peptide bond, the only other type of covalent bond involved in linking amino-acids is the disulphide (–S–S–) bond, which can be formed between two cysteine side-chains under oxidising conditions. The disulphide bond contributes significantly to the structural stability of an enzyme and more precisely in tertiary structural stabilisation (see below for details; Matthews 1993, Estape et al. 1998).

Detailed studies have shown that certain combinations of α-helices or β-sheet together with turns occur in many proteins. These often-occurring structures have been termed *motifs*, or super-secondary structure (Kabsch and Sander 1983, Adamson et al. 1993). Examples of motifs found in several enzymes are shown in Figure 7.3. These protein folds represent highly stable structural units, and it is believed that they may form nucleating centres in protein folding (Richardson 1981).
Figure 7.3. Common examples of motifs found in proteins.

Certain combinations of α-helices and β-sheets pack together to form compactly folded globular units, each of which is called protein domain with molecular mass of 15,000 to 20,000 Da (Orengo et al. 1997). Domains may be composed of secondary structure and identifiable motifs and therefore represent a higher level of structure than motifs. The most widely used classification scheme of domains has been the four-class system (Fig. 7.4; Murzin et al. 1995). The four classes of protein structure are as follows:

1. All-α-proteins, which have only α-helix structure.
2. All-β-proteins, which have β-sheet structure.
3. α/β-proteins, which have mixed or alternating segments of α-helix and β-sheet structure.
4. $\alpha+\beta$ proteins, which have α-helix and β-sheet structural segments that do not mix but are separated along the polypeptide chain.

While small proteins may contain only a single domain, larger enzymes contain a number of domains. In fact, most enzymes are dimers, tetramers or polymers of several polypeptide chains. Each polypeptide chain is termed 'subunit' and it may be identical or different to the others. The side chains on each polypeptide chain may interact with each other, as well as with water molecules to give the final enzyme structure. The overall organisation of the subunits is known as the *quaternary structure* and therefore the quaternary structure is a characteristic of multi-subunit enzymes. The four levels of enzyme structure are illustrated in Figure 7.5.

THEORY OF ENZYME CATALYSIS AND MECHANISM

In order for a reaction to occur, the reactant molecules must possess sufficient energy to cross a potential energy barrier, which is known as the *activation energy* (Fig. 7.6; Hackney 1990). All reactant molecules have different amounts of energy, but only a small proportion of them have sufficient energy to cross the activation energy of the reaction. The lower the activation energy, the more substrate molecules are able to cross the activation energy. The result is that the reaction rate is increased.

Enzyme catalysis requires the formation of a specific reversible complex between the substrate and the enzyme. This complex is known as the *enzyme–substrate complex* (ES) and provides all the conditions that favour the catalytic event (Hackney 1990, Marti et al. 2004). Enzymes accelerate reactions by lowering the energy required for the formation of a complex of reactants that is competent to produce reaction products. This complex is known as the *transition state complex* of the reaction and is characterised by lower free energy than it would be found in the uncatalysed reaction.

$$E + S \rightleftharpoons ES \rightleftharpoons ES^* \rightleftharpoons EP \rightleftharpoons E + P$$

Scheme 7.3.

The ES must pass to the transition state (ES*). The transition state complex must advance to an *enzyme–product complex* (EP), which dissociates to free enzyme and product (P). This reaction's pathway goes through the transition states TS_1, TS_2 and TS_3. The amount of energy required to achieve the transition state is lowered; hence, a greater proportion of the molecules in the population can achieve the transition state and cross the activation energy (Benkovic and Hammes-Schiffer 2003, Wolfenden 2003). Enzymes speed up the forward and reverse reactions proportionately, so that they have no effect on the equilibrium constant of the reactions they catalyse (Hackney 1990).

Substrate is bound to the enzyme by relatively weak noncovalent forces. The free energy of interaction of the ES complex ranges between -12 to -36 kJ/mole. The intermolecular attractive forces between enzyme–substrate, in general, are of three types: ionic bonds, hydrogen bonds and van der Waals attractions.

Specific part of the protein structure that interacts with the substrate is known as the *substrate binding site* (Fig. 7.7). The substrate binding site is a three-dimensional entity suitably designed as a pocket or a cleft to accept the structure of the substrate in three-dimensional terms. The binding residues are defined as any residue with any atom within 4 Å of a bound substrate. These binding residues that participate in the catalytic event are known as the *catalytic-residues* and form the *active-site*. According to Bartlett et al. (Bartlett et al. 2002), a residue is defined as catalytic if any of the following take place:

1. Direct involvement in the catalytic mechanism, for example as a nucleophile.
2. Exerting an effect, that aids catalysis, on another residue or water molecule, which is directly involved in the catalytic mechanism.
3. Stabilisation of a proposed transition-state intermediate.
4. Exerting an effect on a substrate or cofactor that aids catalysis, for example by polarising a bond that is to be broken.
Figure 7.4. The four-class classification system of domains. (**A**) The $\alpha + \beta$ class (structure of glycyl-tRNA synthetase α-chain). (**B**) the all α class (structure of the hypothetical protein (Tm0613) from *Thermotoga maritima*). (**C**) The α/β class (structure of glycerophosphodiester phosphodiesterase). (**D**) The all β class (structure of allantoicase from *Saccharomyces cerevisiae*).

Despite the impression that the enzyme's structure is static and locked into a single conformation, several motions and conformational changes of the various regions always occur (Hammes 2002). The extent of these motions depends on many factors, including temperature, the properties of the solvating medium, the presence or absence of substrate and product (Hammes 2002). The conformational changes undergone by the enzyme play an important role in controlling the catalytic cycle. In some enzymes, there are significant movements of the binding residues, usually on surface loops, and in other cases, there are larger conformational changes. Catalysis takes place in the closed form and the enzyme opens again to release the product. This favoured model that explains enzyme catalysis and substrate interaction is the so-called *induced fit hypothesis* (Anderson et al. 1979, Joseph et al. 1990). In this hypothesis, the initial interaction between enzyme and substrate rapidly induces conformational changes in the shape of the active site, which results in a new shape of the active site that brings catalytic residues close to substrate bonds to be altered (Fig. 7.8). When binding of the substrate to the enzyme takes place, the shape adjustment triggers catalysis by generating transition-state complexes. This hypothesis helps to explain why enzymes only catalyse specific reactions (Anderson et al. 1979, Joseph et al. 1990). This basic cycle has been seen in many different enzymes, including triosephosphate isomerase, which uses a small hinged loop to close the active site (Joseph et al. 1990) and kinases, which use two large lobes moving towards each other when the substrate binds (Anderson et al. 1979).
Figure 7.5. Schematic representation of the four levels of protein structure.

COENZYMES, PROSTHETIC GROUPS AND METAL ION COFACTORS

Non-protein groups can also be used by enzymes to affect catalysis. These groups, called *cofactors*, can be organic or inorganic and are divided into three classes: coenzymes, prosthetic groups and metal ion cofactors (McCormick 1975). Prosthetic groups are tightly bound to an enzyme through covalent bond. Coenzymes bind to enzyme reversibly and associate and dissociate from the enzyme during each catalytic cycle and therefore may be considered as co-substrates. An enzyme containing a cofactor or prosthetic group is termed as *holoenzyme*. Coenzymes can be broadly classified into three main groups: coenzymes that transfer groups onto substrate, coenzymes that accept and donate electrons and compounds that activate substrates (Table 7.2). Metal ions such as Ca^{+2}, Mg^{+2}, Zn^{+2}, Mn^{+2}, Fe^{+2} and Cu^{+2} may in some cases act as cofactors. These may be bound to the enzyme by simple coordination with electron-donating atoms of side chains (imidazole of His, –SH group of Cys, carboxy-

late O^- of Asp and Glu). In some cases, metals, such as Mg^{+2}, are associated with the substrate rather than the enzyme. For example, Mg-ATP is the true substrate for kinases (Anderson et al. 1979). In other cases, metals may form part of a prosthetic group in which they are bound by coordinate bonds (e.g. heme; Table 7.2) in addition to side-chain groups. Usually, in this case, metal ions participate in electron transfer reactions.

KINETICS OF ENZYME-CATALYSED REACTIONS

The term enzyme kinetics implies a study of the velocity of an enzyme-catalysed reaction and of the various factors that may affect this (Moss 1988). An extensive discussion of enzyme kinetics would stay too far from the central theme of this chapter, but some general aspects will be briefly considered.

The concepts underlying the analysis of enzyme kinetics continue to provide significant information for understanding in vivo function and metabolism and for the development and clinical use of drugs aimed at selectively altering rate constants and interfering with the progress of disease states (Bauer et al. 2001). Central scope of any study of enzyme kinetics is knowledge of the way in which reaction velocity is altered by changes in the concentration of the enzyme's substrate and of the simple mathematics underlying this (Wharton 1983, Moss 1988, Watson and Dive 1994). As we have already discussed, the enzymatic reactions proceed through an intermediate ES in which each molecule of enzyme is combined, at any given instant during the reaction, with one substrate molecule. The reaction between enzyme and substrate to form the ES is reversible. Therefore, the overall enzymatic reaction can be shown as

$$E + S \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} ES \xrightarrow{k_{+2}} E + P$$
Scheme 7.4.

where k_{+1}, k_{-1} and k_{+2} are the respective rate constants. The reverse reaction concerning the conversion of product to substrate is not included in this scheme. This is allowed at the beginning of the reaction when there is no, or little, product present. In 1913, biochemists Michaelis and Menten suggested that if the reverse reaction between E and S is sufficiently rapid, in comparison with the breakdown of ES complex to form product, the latter reaction will have a negligible effect on the concentration of the ES complex. Consequently, E, S and ES will be in equilibrium, and the rates of formation and breakdown of ES will be equal. On the basis of these assumptions Michaelis and Menten produced the following equation:

$$v = \frac{V_{max} \cdot [S]}{K_m + [S]}$$

This equation is a quantitative description of the relationship between the rate of an enzyme-catalysed reaction (u) and the concentration of substrate [S]. The parameters V_{max} and K_m are
Figure 7.6. A schematic diagram showing the free energy profile of the course of an enzyme catalysed reaction involving the formation of enzyme–substrate (ES) and enzyme–product (EP) complexes. The catalysed reaction pathway goes through the transition states TS$_1$, TS$_2$, and TS$_3$, with standard free energy of activation $\triangle G_c$, whereas the uncatalysed reaction goes through the transition state TS$_u$ with standard free energy of activation $\triangle G_u$.

constants at a given temperature and a given enzyme concentration. The K_m or Michaelis constant is the substrate concentration at which $v = V_{max}/2$ and its usual unit is M. The K_m provides us with information about the substrate *binding affinity* of the enzyme. A high K_m indicates a low affinity and vice versa (Moss 1988, Price and Stevens 1999).

The V_{max} is the maximum rate of the enzyme-catalysed reaction and it is observed at very high substrate concentrations where all the enzyme molecules are saturated with substrate, in the form of ES complex. Therefore

$$V_{max} = k_{cat}[E_t]$$

where $[E_t]$ is the total enzyme concentration and k_{cat} is the rate of breakdown of the ES complex (k_{+2} in the equation), which is known as the *turnover number*. k_{cat} represents the maximum number of substrate molecules that the enzyme can convert to product in a set time. The K_m depends on the particular enzyme and substrate being used and on the temperature, pH, ionic strength, etc. However, note that K_m is independent of the enzyme concentration, whereas V_{max} is proportional to enzyme concentration. A plot of the initial rate (v) against initial substrate concentration ($[S]$) for a reaction obeying the Michaelis–Menten

kinetics has the form of a rectangular hyperbola through the origin with asymptotes $v = V_{max}$ and $[S] = -K_m$ (Fig. 7.9A). The term *hyperbolic kinetics* is also sometimes used to characterise such kinetics.

There are several available methods for determining the parameters from the Michaelis–Menten equation. A better method for determining the values of V_{max} and K_m was formulated by Hans Lineweaver and Dean Burk and is termed the Lineweaver-Burk (LB) or *double reciprocal plot* (Fig. 7.9B). Specifically, it is a plot of $1/v$ versus $1/[S]$, according to the equation:

$$\frac{1}{v} = \frac{K_m}{V_{max}} \cdot \frac{1}{[S]} + \frac{1}{V_{max}}$$

Such a plot yields a straight line with a slope of K_m/V_{max}. The intercept on the $1/v$ axis is $1/V_{max}$ and the intercept on the $1/[S]$ axis is $-1/K_m$.

The rate of an enzymatic reaction is also affected by changes in pH and temperature (Fig. 7.10). When pH is varied, the velocity of reaction in the presence of a constant amount of enzyme is typically greatest over a relatively narrow range of pH. Since enzymes are proteins, they possess a large number of ionic groups, which are capable of existing in different ionic forms (Labrou et al. 2004a). The existence of a fairly narrow pH-optimum for
Figure 7.7. The substrate binding site of maize glutathione *S*-transferase. The binding residues are depicted as sticks, whereas the substrate is depicted in a space fill model. Only Ser 11 is involved directly in catalysis and is considered as catalytic residue.

**Figure 7.8.** A schematic representation of the induced fit hypothesis.

most enzymes suggests that one particular ionic form of the enzyme molecule, out of the many that it can potentially exist, is the catalytically active one. The effect of pH changes on *v* is reversible, except after exposure to extremes of pH at which denaturation of the enzyme may occur.

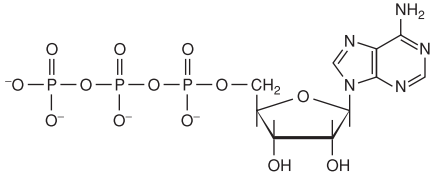
The rate of an enzymatic reaction increases with increasing temperature. Although there are significant variations from one enzyme to another, on average, for each 10°C rise in temperature, the enzymatic activity is increased by an order of two. After exposure of the enzyme to high temperatures (normally greater that 65°C), denaturation of the enzyme may occur and the enzyme activity decreased. The Arrhenius equation

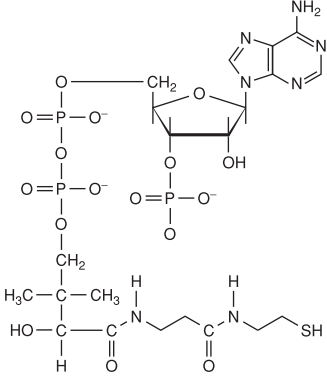
$$Log V_{\max} = \frac{-E_a}{2{,}303RT} + A$$

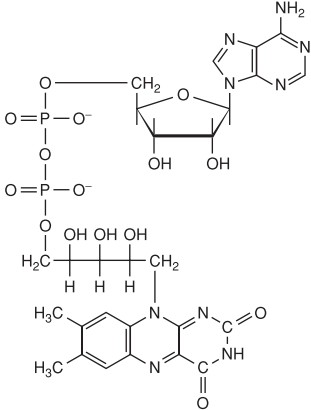
provides a quantitative description of the relationship between the rate of an enzyme-catalysed reaction ($V_{\max}$) and the temperature (T). Where E_a is the activation energy of the reaction, R is the gas constant, and A is a constant relevant to the nature of the reactant molecules.

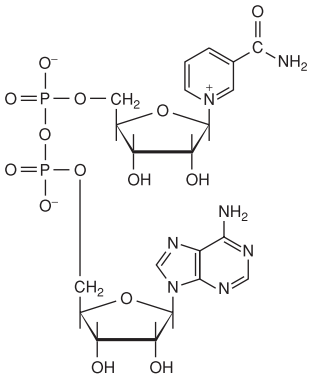
The rates of enzymatic reactions are affected by changes in the concentrations of compounds other than the substrate. These modifiers may be activators, that is they increase the rate of reaction or their presence may inhibit the enzyme's activity. Activators and inhibitors are usually small molecules or even ions. Enzyme inhibitors fall into two broad classes: those causing irreversible inactivation of enzymes and those whose inhibitory effects can be reversed. Inhibitors of the first class bind covalently to the enzyme so that physical methods of separating the two are ineffective. Reversible inhibition is characterised by the existence of equilibrium between enzyme and inhibitor (I):

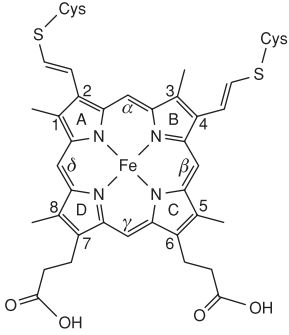
$$E + I \rightleftharpoons EI$$
Scheme 7.5.

The equilibrium constant of the reaction, K_i, is given by the equation:










$$K_i = \frac{[ES]}{[E][I]}$$

K_i is a measure of the affinity of the inhibitor for the enzyme. Reversible inhibitors can be divided into three main categories: competitive inhibitors, non-competitive inhibitors and uncompetitive inhibitors. The characteristic of each type of inhibition and their effect on the kinetic parameters K_m and $V_{\max}$ are shown in Table 7.3.

THERMODYNAMIC ANALYSIS

Thermodynamics is the science that deals with energy. Chemical bonds store energy, as the subatomic particles are being attracted and chemical reactions are occurred with energy changes. Originally, thermodynamic laws were used to analyse and characterise mechanical systems, but the kinetic molecular theory

Table 7.2. The Structure of Some Common Coenzymes: Adenosine Triphosphate (ATP), Coenzyme A (CoA), Flavin Adenine Dinucleotide (FAD), Nicotinamide Adenine Dinucleotide (NAD$^+$) and Heam c

Cofactor	Type of Reactions Catalysed	Structure
Adenosine triphosphate (ATP)	Phosphate transfer reactions (e.g. kinases)	
Coenzyme A (CoA)	Acyl transfer reactions (transferases)	
Flavin adenine dinucleotide (FAD)	Redox reactions (reductases)	
Nicotinamide adenine dinucleotide (NAD$^+$)	Redox reactions (e.g. dehydrogenases)	
Heam c	Activate substrates

The substrate concentration, which gives a rate of half the maximum reaction velocity, is equal to the K_m. (**B**) The Lineweaver-Burk plot. The intercept on the $1/v$ axis is $1/V_{max}$, the intercept on the 1/[S] axis is $-1/K_m$ and the slope is K_m/V_{max}.

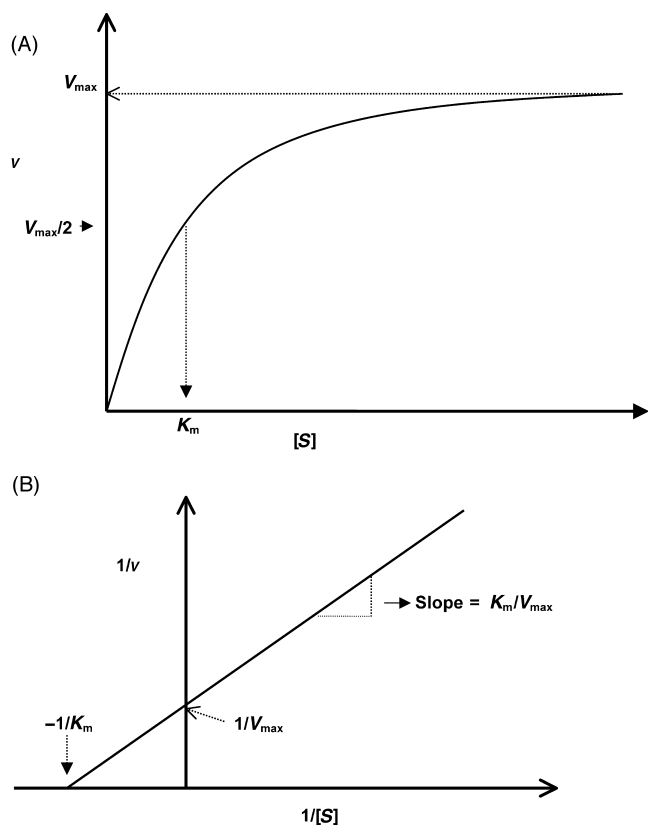

Figure 7.10. Relationship of the activity–pH and activity–temperature for a putative enzyme.

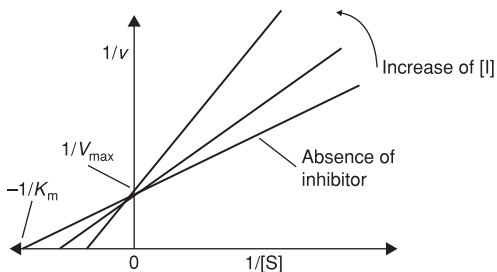
(Eblin 1964) suggests that molecules are in constant motion, which obey the same laws of mechanics as macroscopic objects. Since enzymes are biomolecules, which catalyse chemical reactions, they contribute to the energetic background of a chemical system. As a result, enzymes are directly related to thermodynamic parameters.

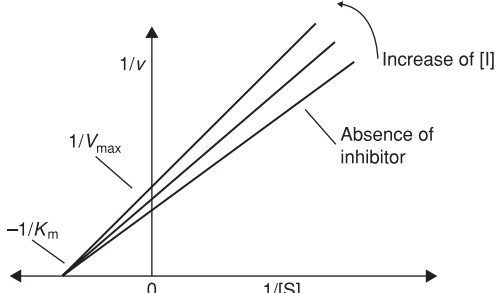
In this section, we will focus on the most representative thermodynamic parameters that are useful, in order to describe experimental data. The fundamental thermodynamic parameters are the Helmholtz free energy (F), the entropy (S) and the enthalpy (H). Free energy (F) correlates the energy (E) of a system with its entropy (S): $F = E - TS$, where T is the temperature. The entropy (S) of a system is the range of its disorder and the thermodynamic definition is (Rakintzis 1994) (the symbol q is used to represent the amount of heat absorbed by a system):

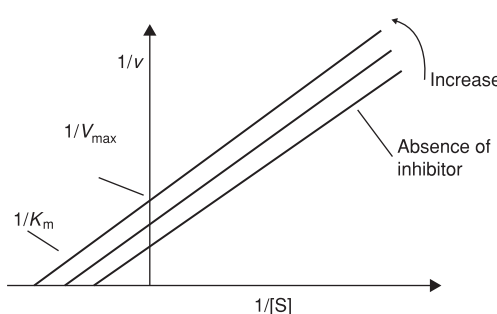
$$S = \int \frac{q}{T} dT \Leftrightarrow S = q \ln(T)$$

Furthermore, enthalpy is a constitutive function of pressure (P) and temperature (T), and energy (E) is a constitutive func-

tion of volume (V) and temperature (T), respectively (Rakintzis 1994):

$$H = f(P, T)$$






$$dH = \left[\frac{\partial H}{\partial P}\right]_T dP + \left[\frac{\partial H}{\partial T}\right]_P dT$$

$$E = f(V, T)$$

$$dE = \left[\frac{\partial E}{\partial V}\right]_T dV + \left[\frac{\partial E}{\partial T}\right]_V dT$$

At this point, we have to emphasise that in biological systems, a normal experiment deals with a constant pressure (atmospheric pressure) and not with a constant volume. This means, that we determine not a change of energy (E) of a studied body (e.g. enzyme), but a change in its enthalpy: $H = E + PV$. However, the quantity (PV) is considered insignificant in case that we study a protein for instance, because the volume per molecule is too small. Hence, there is no difference between H and E, and we can refer both of them simply as "energy' (Finkelstein and Ptitsyn 2002). Likewise, there is no difference between Helmholtz free energy ($F = E - TS$) and Gibb's free energy ($G = H - TS$), since we consider that H is equivalent to E. As a result, we

Table 7.3. The Characteristic of Each Type of Inhibition and Their Effect on the Kinetic Parameters K_m and V_{max}

Inhibitor Type	Binding Site on Enzyme	Kinetic Effect
Competitive Inhibitor	The inhibitor specifically binds at the enzyme's catalytic site, where it competes with substrate for binding: E $\underset{-S}{\overset{+S}{\rightleftharpoons}}$ ES $\rightarrow$ E + P $+I \Updownarrow -I$ EI	 K_m is increased; V_{max} is unchanged. LB equation: $$\frac{1}{v} = \frac{K_m}{V_{max}}\left(1 + \frac{[I]}{Ki}\right)\frac{1}{[S]} + \frac{1}{V_{max}}$$
Non-competitive Inhibitor	The inhibitor binds to E or to the ES complex (may form an ESI complex) at a site other than the catalytic. Substrate binding is unchanged, whereas ESI complex cannot form products. E $\underset{-S}{\overset{+S}{\rightleftharpoons}}$ ES $\rightarrow$ E + P $+I \Updownarrow -I \qquad +I \Updownarrow -I$ EI $\underset{-S}{\overset{+S}{\rightleftharpoons}}$ ES $\rightleftharpoons$ E + P	 K_m is unchanged; V_{max} is decreased proportionately to inhibitor concentration. LB equation: $$\frac{1}{v} = \frac{K_m}{V_{max}}\cdot\left(1 + \frac{[I]}{K_i}\right)\cdot\frac{1}{[S]} + \frac{1}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)$$
Uncompetitive Inhibitor	Binds only to ES complexes at a site other than the catalytic site. Substrate binding alters enzyme structure, making inhibitor-binding site available: E $\underset{-S}{\overset{+S}{\rightleftharpoons}}$ ES $\rightarrow$ E + P $+I \Updownarrow -I$ EIS	 K_m and V_{max} are decreased. LB equation: $$\frac{1}{v} = \frac{K_m}{V_{max}}\cdot\frac{1}{[S]} + \frac{1}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)$$

can refer both F and G as 'free energy' (Finkelstein and Ptitsyn 2002). Eventually, when we study the thermodynamic behaviour of an enzyme, regarding its structural stability or its functionality, we have to do with Gibb's free energy (G), entropy (S) and enthalpy (H).

As far as experimental procedures are concerned, someone can use two equations in order to measure the thermodynamic parameters, applying temperature differentiation experimental protocols (Kotzia and Labrou 2005). These equations are the Arrhenius (Equation 4) and the Eyring equations, which basically describe the temperature dependence of reaction state. So, considering an enzymic reaction as a chemical reaction, which is characterised by a transition state, we can efficiently use the Eyring's equation. This equation is based on transition state

model, whose principles are (i) there is a thermodynamic equilibrium between the transition state and the state of reactants at the top of the energy barrier and (ii) the rate of chemical reaction is proportional to the concentration of the particles in the high-energy transition state.

Combining basic kinetic expressions, which describe a simple chemical reaction:

$$A + B \longrightarrow C$$

Scheme 7.6.

---

and thermodynamic equations, such as (Finkelstein and Ptitsyn 2002)

$$\Delta G = -RT \ln k$$
$$\Delta G = \Delta H - T \Delta S$$

Eyring's equation is formed:

$$k = \frac{k_\beta T}{h} e^{-(\frac{\Delta G}{RT})} = \frac{k_\beta T}{h} e^{-(\frac{\Delta H}{RT} - \frac{\Delta S}{R})}$$

where k is the reaction velocity, R is the universal gas constant (8.3145 $J \cdot mol^{-1}$ K), k_B the Boltzmann's constant ($1.381 \cdot 10^{-23}$ $J \cdot K^{-1}$), h is the Plank constant ($6.626 \cdot 10^{-34}$ $J \cdot s$) and T is the absolute temperature in degrees Kelvin (K). If we compare Eyring's equation and Arrhenius equation (Laidler 1984), we can realise that E and ΔH are parallel quantities, as we concluded above. Eyring's equation is an appropriate and useful tool, which allows us to simplify the complicated meaning of thermodynamics and, simultaneously, to interpret experimental data to physical meanings.

Enzyme Dynamics During Catalysis

Multiple conformational changes and intramolecular motions appear to be a general feature of enzymes (Agarwal et al. 2002). The structures of proteins and other biomolecules are largely maintained by non-covalent forces and are therefore subject to thermal fluctuations ranging from local atomic displacements to complete unfolding. These changes are intimately connected to enzymatic catalysis and are believed to fulfil a number of roles in catalysis: enhanced binding of substrate, correct orientation of catalytic groups, removal of water from the active site and trapping of intermediates. Enzyme conformational changes may be classified into four types (Gutteridge and Thornton 2004): (i) domain motion, where two rigid domains, joined by a flexible hinge, move relative to each other; (ii) loop motion, where flexible surface loops (2–10 residues) adopt different conformations; (iii) side chain rotation, which alters the position of the functional atoms of the side chain and (iv) secondary structure changes.

Intramolecular motions in biomolecules are usually very fast (picosecond–nanosecond) local fluctuations. The flexibility associated with such motions provides entropic stabilisation of conformational states (Agarwal et al. 2002). In addition, there are also slower- (microsecond–millisecond) and larger-scale, thermally activated, transitions. Large-scale conformational changes are usually key events in enzyme regulation.

ENZYME PRODUCTION

In the past, enzymes were isolated primarily from natural sources, and thus a relatively limited number of enzymes were available to the industry (Aehle 2007). For example, of the hundred or so enzymes being used industrially, over one half are from fungi and yeast and over a third are from bacteria, with the remainder divided between animal (8%) and plant (4%) sources (Panke and Wubbolts 2002, van Beilen and Li 2002, Bornscheuer 2005). Today, with the recent advances of molecular biology and genetic engineering, several expression systems were developed and exploited and used for the commercial production of several therapeutic (Mcgrath 2005), analytical or industrial enzymes (van Beilen and Li 2002, Kirk et al. 2002, Otero and Nielsen 2010). These systems have not only improved the efficiency, availability and cost with which enzymes can be produced, but they have also improved their quality (Labrou and Rigden 2001, Andreadeli et al. 2008, Kapoli et al. 2008, Kotzia and Labrou 2009, Labrou 2010).

Enzyme Heterologous Expression

There are two basic steps involved in the assembly of every heterologous expression system:

1. The introduction of the DNA, encoding the gene of interest, into the host cells, which requires: (i) the identification and isolation of the gene of the protein we wish to express, (ii) insertion of the gene into a suitable expression vector and (iii) introduction of the expression vector into the selected cell system that will accommodate the heterologous protein.
2. The optimisation of protein expression by taking into account the effect of various factors such as growing medium, temperature, and induction period.

A variety of vectors able to carry the DNA into the host cells are available, ranging from plasmids, cosmids, phagemids, viruses as well as artificial chromosomes of bacterial, yeast or human origin (BAC, YAC or HAC, respectively; Grimes and Monaco 2005, Monaco and Moralli 2006, Takahashi and Ueda 2010). The vectors are either integrated into the host chromosomal DNA or remain in an episomal form. In general, expression vectors have the following characteristics (Fig. 7.11):

1. Polylinker: it contains multiple restriction sites that facilitate the insertion of the desired gene into the vector.
2. Selection marker: encodes for a selectable marker, allowing the vector to be maintained within the host cell under conditions of selective pressure (i.e. antibiotic).
3. Ori: a sequence that allows for the autonomous replication of the vector within the cells.
4. Promoter: inducible or constitutive, that regulates RNA transcription of the gene of interest.
Figure 7.11. Generalised heterologous gene expression vector. Polylinker sequence (multiple cloning site (MCS)), promoter (P$^{euk/pro}$), terminator (T$^{euk/pro}$), selectable marker (prokaryotic and/or eukaryotic – M$^{euk/pro}$), and origin of replication (eukaryotic and/or prokaryotic – Ori$^{euk/pro}$).

5. Terminator: a strong terminator sequence that ensures that the RNA polymerase disengages and does not continue to transcribe other genes located downstream.

Vectors are usually designed with mixed characteristics for expression in both prokaryotic and eukaryotic host cells (Brondyk 2009, Demain and Vaishnav 2009). Artificial chromosomes are designed for cloning of very large segments of DNA (100 kb), usually for mapping purposes, and contain host-specific telomeric and centromeric sequences. These sequences permit the proper distribution of the vectors to the daughter cells during cell division and increase chromosome stability (Fig. 7.12).

The Choice of Expression System

There are two main categories of expression systems: eukaryotic and prokaryotic (Demain and Vaishnav 2009). The choice of a suitable expression system involves the consideration of several important factors, such as protein yield, proper folding, post-translational modifications (e.g. phosphorylation, glycosylation), industrial applications of the expressed protein, as well as economic factors. For these reasons, there is no universally applied expression system. A comparison of the most commonly used expression systems is shown in Table 7.4.

Bacterial Cells

Expression of heterologous proteins in bacteria remains the most extensively used approach for the production of heterologous proteins (Zerbs et al. 2009), such as cytokines (Tang et al. 2006, Rabhi-Essafi et al. 2007), membrane proteins (Butzin
Figure 7.12. Artificial chromosome cloning system. Initially, the circular vector is digested with restriction endonucleases (RE) for linearisation and then ligated with size-fractionated DNA (≈100 kb). The vector contains centromeric and telomeric sequences, which assure chromosome-like propagation within the cell, as well as selection marker sequences for stable maintenance. Origin of replication (eukaryotic or prokaryotic – Ori$^{euk/pro}$), selectable marker (eukaryotic or prokaryotic – M$^{euk/pro}$), centromeric sequence (C), and telomeric sequence (T).

et al. 2009, Zoonens and Miroux 2010), enzymes (Melissis et al. 2006, Kotzia and Labrou 2007, Melissis et al. 2007, Andreadeli et al. 2008, Wu et al. 2009, Okino et al. 2010), antibodies (Kwong and Rader 2009, Xiong et al. 2009) and antigens (viral or non-viral; Donayre-Torres et al. 2009, Liu et al. 2009a, Vahedi et al. 2009, Ebrahimi et al. 2010) at both laboratory and industrial scale (Koehn and Hunt 2009, Sahdev et al. 2008, Peti and Page 2007, Jana and Deb 2005). Bacteria can be grown inexpensively and genetically manipulated very easily. They can reach very high densities rapidly and express high levels of recombinant proteins, reaching up to 50% of the total protein. However, in many cases, high-level expression correlates with poor quality. Often, the expressed protein is accumulated in the form of insoluble inclusion bodies (misfolded protein aggregate) and additional, sometimes labour-intensive, genetic manipulation or re-solubilisation/refolding steps are required (Burgess 2009). Bacterial cells do not possess the eukaryotes' extensive post-translational modification system (such as *N*- or

Table 7.4. Comparison of the Main Expression Systems

	Bacteria	Yeast	Fungi	Insect Cells	Mammalian Cells	Transgenic Plants	Transgenic Animals
Developing time	Short	Short	Short	Intermediate	Intermediate	Intermediate	Long
Costs for downstream processing	+++	++	++	++	++	++	++
Levels of expression	High	Intermediate	Intermediate	Intermediate	Low	Low	Low
Recombinant protein stability	+/−	+/−	+/−	+/−	+/−	+++	+/−
Production volume	Limited	Limited	Limited	Limited	Limited	Unlimited	Unlimited
Postranslational modifications (disulphide bond formation, glycosylation, etc.)	No	Yes	Yes	Yes	Yes	Yes	Yes
'Human-type' glycosylation	No	No	No	No	Yes	No	Yes
Folding capabilities	−	++	+++	+++	+++	+++	+++
Contamination level (pathogens, EPL, etc.)	++	−	−	−	++	−	++

O-glycosylation), a serious disadvantage, when post-translational modifications are essential to the protein's function (Zhang et al. 2004). However, they are capable of a surprisingly broad range of covalent modifications such as acetylation, amidation and deamidation, methylation, myristylation, biotinylation and phosphorylation.

Mammalian Cells

Mammalian cells are the ideal candidate for expression hosts (Engelhardt et al. 2009, Hacker et al. 2009) when post-translational modifications (*N*- and *O*-glycosylation, disulfide bond formation) are a critical factor for the efficacy of the expressed protein (Baldi et al. 2007, Werner et al. 2007, Durocher and Butler 2009, Geisse and Fux 2009, Hacker et al. 2009). Despite substantial limitations, such as high cost, low yield, instability of expression and time-consuming, a significant number of proteins (e.g. cytokines; Fox et al. 2004, Sunley et al. 2008, Suen et al. 2010), antibodies (Kim et al. 2008, Chusainow et al. 2009), enzymes (Zhuge et al. 2004), viral antigens (Holzer et al. 2003), blood factors and related proteins (Halabian et al. 2009, Su et al. 2010) are produced in this system because it offers very high product fidelity. However, oligosaccharide processing is species- and cell type-dependent among mammalian cells and differences in the glycosylation pattern have been reported in rodent cell lines and human tissues. The expressed proteins are usually recovered in a bioactive, properly folded form and secreted into the cell culture fluids.

Yeast

Yeast is a widely used expression system with many commercial, medical and basic research applications. The fact that the yeast is the most intensively studied eukaryote at the genetic/molecular level makes it an extremely advantageous expression system (Idiris et al. 2010). Being unicellular organism, it retains the

advantages of bacteria (low cultivation cost, high doubling rate, ease of genetic manipulation, ability to produce heterologous proteins in large-scale quantities) combined with the advantages of higher eukaryotic systems (post-translational modifications). The vast majority of yeast expression work has focused on the well-characterised baker's yeast *Saccharomyces cerevisiae* (Holz et al. 2003, Terpitz et al. 2008, Joubert et al. 2010), but a growing number of non-*Saccharomyces* yeasts are becoming available as hosts for recombinant polypeptide production, such as *Hansenula polymorpha*, *Candida boidinii*, *Kluyveromyces lactis*, *Pichia pastoris* (Cregg et al. 2000, Jahic et al. 2006, van Ooyen et al. 2006, Yurimoto and Sakai 2009), *Schizosaccharomyces pombe* (Alberti et al. 2007, Ahn et al. 2009, Takegawa et al. 2009), *Schwanniomyces occidentalis* and *Yarrowia lipolytica* (Madzak et al. 2004, 2005, Bankar et al. 2009). As in bacteria, expression in yeast relies on episomal or integrated multi-copy plasmids with tightly regulated gene expression. Despite these advantages, expressed proteins are not always recovered in soluble form and may have to be purified from inclusion bodies. Post-translational modifications in yeast differ greatly from mammalian cells (Jacobs and Callewaert 2009, Hamilton and Gerngross 2007). This has sometimes proven to be a hindrance when high fidelity of complex carbohydrate modifications found in eukaryotic proteins appears to be important in many medical applications. Yeast cells do not add complex oligosaccharides and are limited to the high-mannose-type carbohydrates. These higher order oligosaccharides are possibly immunogenic and could potentially interfere with the biological activity of the protein.

Filamentous Fungi

Filamentous fungi have been extensively used for studies of eukaryotic gene organisation, regulation and cellular differentiation. Additionally, fungi belonging to the genus *Aspergillus* and *Penicillium* are of significant industrial importance because

of their applications in food fermentation and their ability to secrete a broad range of biopolymer degrading enzymes and to produce primary (organic acids) and secondary metabolites (antibiotics, vitamins). The extensive genetic knowledge as well as the already well-developed fermentation technology has allowed for the development of heterologous protein expression systems (Nevalainen et al. 2005, Wang et al. 2005) expressing fungal (e.g. glucoamylase (Verdoes et al. 1993), propyl aminopeptidase (Matsushita-Morita et al. 2009)) or mammalian (e.g. human interleukin-6 (Contreras et al. 1991), antitrypsin (Chill et al. 2009), lactoferrin (Ward et al. 1995), bovine chymosin (Ward et al. 1990, Cardoza et al. 2003)) proteins of industrial and clinical interest using filamentous fungi as hosts. However, the expression levels of mammalian proteins expressed in *Aspergillus* and *Trichoderma* species are low compared to homologous proteins. Significant advances in heterologous protein expression have dramatically improved the expression efficiency by fusing the heterologous gene to the 3′-end of a highly expressed homologous gene (mainly glucoamylase). Even so, limitations in protein folding, post-translational modifications, translocation and secretion as well as secretion of extracellular proteases could pose a significant hindrance for the production of bioactive proteins (Gouka et al. 1997, Nevalainen et al. 2005, Lubertozzi and Keasling 2009).

Insect Cells

Recombinant baculoviruses are widely used as a vector for the expression of recombinant proteins in insect cells (Hitchman et al. 2009, Jarvis 2009, Trometer and Falson 2010), such as enzymes (Zhao et al. 2010), immunoglobulins (Iizuka et al. 2009), viral antigens (Takahashi et al. 2010) and transcription factors (Fabian et al. 1998). The recombinant genes are usually expressed under the control of the polyhedrin or *p10* promoter of the *Autographa californica* nuclear polyhedrosis virus (AcNPV) in cultured insect cells of *Spodoptera frugiperda* (Sf9 cells) or in insect larvae of *Lepidopteran* species infected with the recombinant baculovirus containing the gene of interest. The polyhedron and p10 genes possess very strong promoters and are highly transcribed during the late stages of the viral cycle. Usually, the recombinant proteins are recovered from the infected insect cells in soluble form and targeted in the proper cellular environment (membrane, nucleus and cytoplasm). Insect cells have many post-translational modification, transport and processing mechanisms found in higher eukaryotic cells (Durocher and Butler 2009), although their glycosylation efficiency is limited and they are not able to process complex-type oligosaccharides containing fucose, galactose and sialic acid.

Dictyostelium discoideum

Recently, the cellular slime mould *Dictyostelium discoideum,* a well-studied single-celled organism, has emerged as a promising eukaryotic alternative system (Arya et al. 2008b) for the expression of recombinant proteins (e.g. human antithrombin III; Dingermann et al. 1991, Tiltscher and Storr 1993, Dittrich et al. 1994) and enzymes (e.g. phosphodiesterase; Arya et al.

2008a). Its advantage over other expression systems lies in its extensive post-translational modification system (glycosylation, phosphorylation, acylation), which resembles that of higher eukaryotes (Jung and Williams 1997, Jung et al. 1997, Slade et al. 1997). It is a simple organism with a haploid genome of 5×10^7 bp and a life cycle that alternates between single-celled and multicellular stages. Recombinant proteins are expressed from extrachromosomal plasmids (*Dictyostelium discoideum* is one of a few eukaryotes that have circular nuclear plasmids) rather than being integrated in the genome (Ahern et al. 1988). The nuclear plasmids can be easily genetically manipulated and isolated in a one-step procedure, as in bacteria. This system is ideally suited for the expression of complex glycoproteins and although it retains many of the advantages of the bacterial (low cultivation cost) and mammalian systems (establishment of stable cell lines, glycosylation), the development of this system at an industrial scale is hampered by the relatively low productivity, compared to bacterial systems.

Trypanosomatid Protozoa

A newly developed eukaryotic expression system is based on the protozoan lizard parasites of the *Leishmania* and *Trypanosoma* species (Basile and Peticca 2009). Its gene and protein regulation and editing mechanisms are remarkably similar to those of higher eukaryotes and include the capability of 'mammalian-like' glycosylation. It has a very rapid doubling time and can be grown to high densities in relatively inexpensive medium. The recombinant gene is integrated into the small ribosomal subunit rRNA gene and can be expressed to high levels. Increased expression levels and additional promoter control can be achieved in T7 polymerase-expressing strains. Being a lizard parasite, it is not pathogenic to humans, which makes this system invaluable and highly versatile. Proteins and enzymes of significant interest, such as human tissue plasminogen activator (Soleimani et al. 2007), EPO (Breitling et al. 2002), IFNγ (Tobin et al. 1993) and IL-2 (La Flamme 1995), have been successfully expressed in this system.

Transgenic Plants

The current protein therapeutics market is clearly an area of enormous interest from a medical and economic point of view. Recent advances in human genomics and biotechnology have made it possible to identify a plethora of potentially important drugs or drug targets. Transgenic technology has provided an alternative, more cost-effective bioproduction system than the previously used (*E. coli*, yeast, mammalian cells; Larrick and Thomas 2001, Demain and Vaishnav 2009). The accumulated knowledge on plant genetic manipulation has been recently applied to the development of plant bioproduction systems (Twyman et al. 2005, Boehm 2007, Lienard et al. 2007, Faye and Champey 2008, Sourrouille et al. 2009). Expression in plants could be either constitutive or transient and directed to a specific tissue of the plant (depending on the type of promoter used). Expression of heterologous proteins in plants offers significant advantages, such as low production cost, high biomass

production, unlimited supply and ease of expandability. Plants also have high-fidelity expression, folding and post-translational modification mechanisms, which could produce human proteins of substantial structural and functional equivalency compared to proteins from mammalian expression systems (Gomord and Faye 2004, Joshi and Lopez 2005). Additionally, plant-made human proteins of clinical interest (Schillberg et al. 2005, Twyman et al. 2005, Vitale and Pedrazzini 2005, Tiwari et al. 2009), such as antibodies (Hassan et al. 2008, Ko et al. 2009, De Muynck et al. 2010, Lai et al. 2010), vaccines (Hooper 2009, Alvarez and Cardineau 2010), cytokines (Elias-Lopez et al. 2008) and enzymes (Kermode et al. 2007, Stein et al. 2009), are free of potentially hazardous human diseases, viruses or bacterial toxins. However, there is considerable concern regarding the potential hazards of contamination of the natural gene pool by the transgenes and possible additional safety precautions will raise the production cost.

Transgenic Animals

Besides plants, transgenic technology has also been applied to many different species of animals (mice, cows, rabbits, sheep, goats and pigs; Niemann and Kues 2007, Houdebine 2009). The DNA containing the gene of interest is microinjected into the pronucleus of a single-cell fertilised zygote and integrated into the genome of the recipient; therefore, it can be faithfully passed on from generation to generation. The gene of interest is coupled with a signal targeting protein expression towards specific tissues, mainly the mammary gland, and the protein can therefore be harvested and purified from milk. The proteins produced by transgenic animals are almost identical to human proteins, greatly expanding the applications of transgenic animals in medicine and biotechnology. Several human protein of pharmaceutical value have been produced in transgenic animals, such as haemoglobin (Swanson 1992, Logan and Martin 1994), lactoferrin (Han et al. 2008, Yang et al. 2008), antithrombin III (Yang et al. 2009), protein C (Velander 1992) and fibrinogen (Prunkard 1996), and there is enormous interest for the generation of transgenic tissues suitable for transplantation in humans (only recently overshadowed by primary blastocyte technology (Klimanskaya et al. 2008)). Despite the initial technological expertise required to produce a transgenic animal, the subsequent operational costs are low and subsequent inbreeding ensures that the ability to produce the transgenic protein will be passed on to its offspring. However, certain safety issues have arisen concerning the potential contamination of transgenically produced proteins by animal viruses or prions, which could possibly be passed on to the human population. Extensive testing required by the FDA substantially raises downstream costs.

ENZYME PURIFICATION

Once a suitable enzyme source has been identified, it becomes necessary to design an appropriate purification procedure to isolate the desired protein. The extent of purification required for an enzyme depends on several factors, the most important of which being the degree of enzyme purity required as well as

Table 7.5. Protein Properties Used During Purification

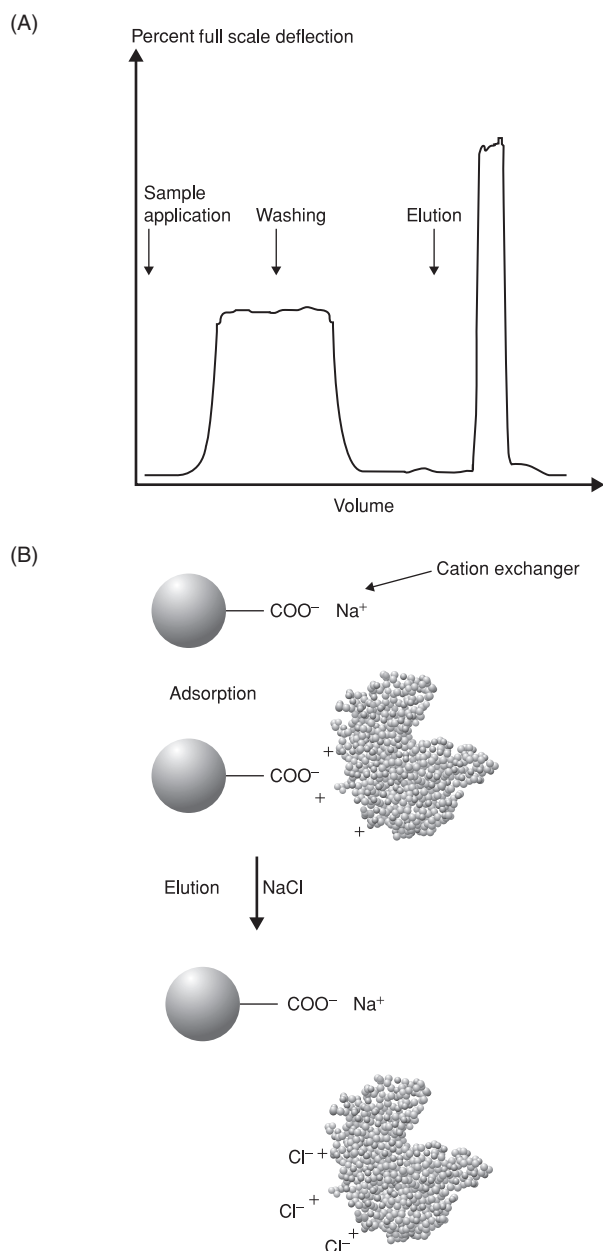
Protein Property	Technique
Solubility	Precipitation
Size	Gel filtration
Charge	Ion exchange
Hydrophobicity	Hydrophobic interaction chromatography
Biorecognition	Affinity chromatography

the starting material, for example the quantity of the desired enzyme present in the initial preparation (Lesley 2001, Labrou and Clonis 2002). For example, industrial enzymes are usually produced as relatively crude preparations. Enzymes used for therapeutic or diagnostic purposes are generally subjected to the most stringent purification procedures, as the presence of compounds other than the intended product may have an adverse clinical impact (Berthold and Walter 1994).

Purification of an enzyme usually occurs by a series of independent steps in which the various physicochemical properties of the enzyme of interest are utilised to separate it progressively from other unwanted constituents (Labrou and Clonis 2002, Labrou et al. 2004b). The characteristics of proteins that are utilised in purification include solubility, ionic charge, molecular size, adsorption properties and binding affinity to other biological molecules. Several methods that exploit differences in these properties are listed in Table 7.5.

Precipitation methods (usually employing $(NH_4)_2SO_4$, polyethyleneglycol or organic solvents) are not very efficient method of purification (Labrou and Clonis 2002). They typically give only a few fold purification. However, with these methods, the protein may be removed from the growth medium or from cell debris where harmful proteases and other detrimental compounds may affect protein stability. On the other hand, *chromatography* is a highly selective separation technique (Regnier 1987, Fausnaugh 1990). A wide range of chromatographic techniques has been used for enzyme purification: size-exclusion chromatography, ion-exchange, hydroxyapatite, hydrophobic interaction chromatography, reverse-phase chromatography and affinity chromatography (Labrou 2003). Of these, ion-exchange and affinity chromatography are the most common and probably the most important (Labrou and Clonis 1994).

Ion-Exchange Chromatography

Ion-exchange resins selectively bind proteins of opposite charge; that is, a negatively charged resin will bind proteins with a net positive charge and vice versa (Fig. 7.13). Charged groups are classified according to type (cationic and anionic) and strength (strong or weak); the charge characteristics of strong ion exchange media do not change with pH, whereas with weak ion-exchange media they do. The most commonly used charged groups include diethylaminoethyl, a weakly anionic exchanger; carboxymethyl, a weakly cationic exchanger; quaternary ammonium, a strongly anionic exchanger; and methyl sulfonate,


(A)

(B)

Figure 7.13. (**A**) Schematic diagram of a chromatogram showing the steps for a putative purification. (**B**) Schematic diagram depicting the principle of ion-exchange chromatography.

a strongly cationic exchanger (Table 7.6; Levison 2003). The matrix material for the column is usually formed from beads of carbohydrate polymers, such as agarose, cellulose or dextrans (Levison 2003).

The technique takes place in five steps (Labrou 2000; Fig. 7.13): *equilibration* of the column to pH and ionic strength conditions suitable for target protein binding; protein *sample application* to the column and reversible adsorption through

counter-ion displacement; *washing* of the unbound contaminating proteins, enzymes, nucleic acids and other compounds; introduction of *elution* conditions in order to displace bound proteins; and *regeneration* and *re-equilibration* of the adsorbent for subsequent purifications. Elution may be achieved either by increasing the salt concentration or by changing the pH of the irrigating buffer. Both methods are used in industry, but raising the salt concentration is by far the most common because it is easier to control (Levison 2003). Most protein purifications are done on anion exchange columns because most proteins are negatively charged at physiological pH values (pH 6–8).

Affinity Chromatography

Affinity chromatography is potentially the most powerful and selective method for protein purification (Fig. 7.14; Labrou and Clonis 1994, Labrou 2003). According to the International Union of Pure and Applied Chemistry, affinity chromatography is defined as a liquid chromatographic technique that makes use of a 'biological interaction' for the separation and analysis of specific analytes within a sample. Examples of these interactions include the binding of an enzyme with a substrate/inhibitor or of an antibody with an antigen or in general the interaction of a protein with a binding agent, known as the 'affinity ligand' (Fig. 7.14; Labrou 2002, 2003, Labrou et al. 2004b). The development of an affinity chromatography-based purification step involves the consideration of the following factors: (i) selection of an appropriate ligand and (ii) immobilisation of the ligand onto a suitable support matrix to make an *affinity adsorbent*. The selection of the immobilised ligand for affinity chromatography is the most challenging aspect of preparing an affinity adsorbent. Certain factors need to be considered when selecting a ligand (Labrou and Clonis 1995, 1996): (i) the specificity of the ligand for the protein of interest, (ii) the reversibility of the interaction with the protein, (iii) its stability against the biological and chemical operation conditions and (iv) the affinity of the ligand for the protein of interest. The binding site of a protein is often located deep within the molecule and adsorbents prepared by coupling the ligands directly to the support exhibit low binding capacities. This is due to steric interference between the support matrix and the protein's binding site. In these circumstances, a 'spacer arm' is inserted between the matrix and ligand to facilitate effective binding (Fig. 7.14). A hexyl spacer is usually inserted between ligand and support by substitution of 1,6-diaminohexane (Lowe 2001).

The ideal matrix should be hydrophilic, chemically and biologically stable and have sufficient modifiable groups to permit an appropriate degree of substitution with the enzyme. Sepharose is the most commonly used matrix for affinity chromatography on the research scale. Sepharose is a commercially available beaded polymer, which is highly hydrophilic and generally inert to microbiological attack (Labrou and Clonis 2002). Chemically, it is an agarose (poly-$\{\beta$-1,3-D-galactose-α-1,4-(3,6-anhydro)-L-galactose$\}$) derivative.

The selection of conditions for an optimum affinity chromatographic purification involves the study of the following factors: (1) choice of adsorption conditions (e.g. buffer composition,

Table 7.6. Functional Groups Used on Ion Exchangers

	Functional Group

pH, ionic strength) to maximise the conditions required for the formation of strong complex between the ligand and the protein to be purified, (2) choice of washing conditions to desorb non-specifically bound proteins and (3) choice of elution conditions to maximise purification (Labrou and Clonis 1995). The elution conditions of the bound macromolecule should be both

Figure 7.14. Schematic diagram depicting the principle of affinity chromatography.

tolerated by the affinity adsorbent and effective in desorbing the biomolecule in good yield and in the native state. Elution of bound proteins is performed in a non-specific or biospecific manner. Non-specific elution usually involves (1) changing the ionic strength (usually by increasing the buffer's molarity or including salt, e.g. KCl or NaCl) and the pH (adsorption generally weakens with increasing pH), (2) altering the polarity of the irrigating buffer by employing, for example ethylene glycol or other organic solvents, if the hydrophobic contribution in the protein-ligand complex is large. Biospecific elution is achieved by inclusion in the equilibration buffer of a suitable ligand, which usually competes with the immobilised ligand for the same binding site on the enzyme/protein (Labrou 2000). Any competing ligand may be used. For example, substrates, products, cofactors, inhibitors or allosteric effectors are all potential candidates as long as they have higher affinity for the macromolecule than the immobilised ligand.

Dye-ligand affinity chromatography represents a powerful affinity-based technique for enzyme and protein purification (Clonis et al. 2000, Labrou 2002, Labrou et al. 2004b). The technique has gained broad popularity due to its simplicity and wide applicability to purify a variety of proteins. The employed dyes as affinity ligands are commercial textile chlorotriazine polysulfonated aromatic molecules, which are usually termed as triazine dyes (Fig. 7.15). Such dye-ligands have found wide applications over the past 20 years as general affinity ligands in the research market to purify enzymes, such as oxidoreductases, decarboxylases, glycolytic enzymes, nucleases, hydrolases, lyases, synthetases and transferases (Scopes 1987). Anthraquinone triazine dyes are probably the most widely used dye-ligands in enzyme and protein purification. Especially the triazine dye Cibacron Blue F3GA (Fig. 7.18) has been widely exploited as an affinity chromatographic tool to separate and purify a variety of proteins (Scopes 1987). With the aim of increasing the specificity of dye-ligands, the biomimetic dye-ligand concept was introduced. According to this concept, new dyes that mimic natural ligands of the targeted proteins are designed by substituting the terminal 2-aminobenzene sulfonate moiety of the dye Cibacron Blue 3GA (CB3GA) for (ή with) a substrate-mimetic moiety (Clonis et al. 2000, Labrou 2002, 2003, Labrou et al. 2004b). These biomimetic dyes exhibit increased purification ability and specificity and provide useful tools for designing simple and effective purification protocols.
Figure 7.15. Structure of several representative triazine dyes: (**A**) Cibacron Blue 3GA, (**B**) Procion Red HE-3B and (**C**) Procion Rubine MX-B.

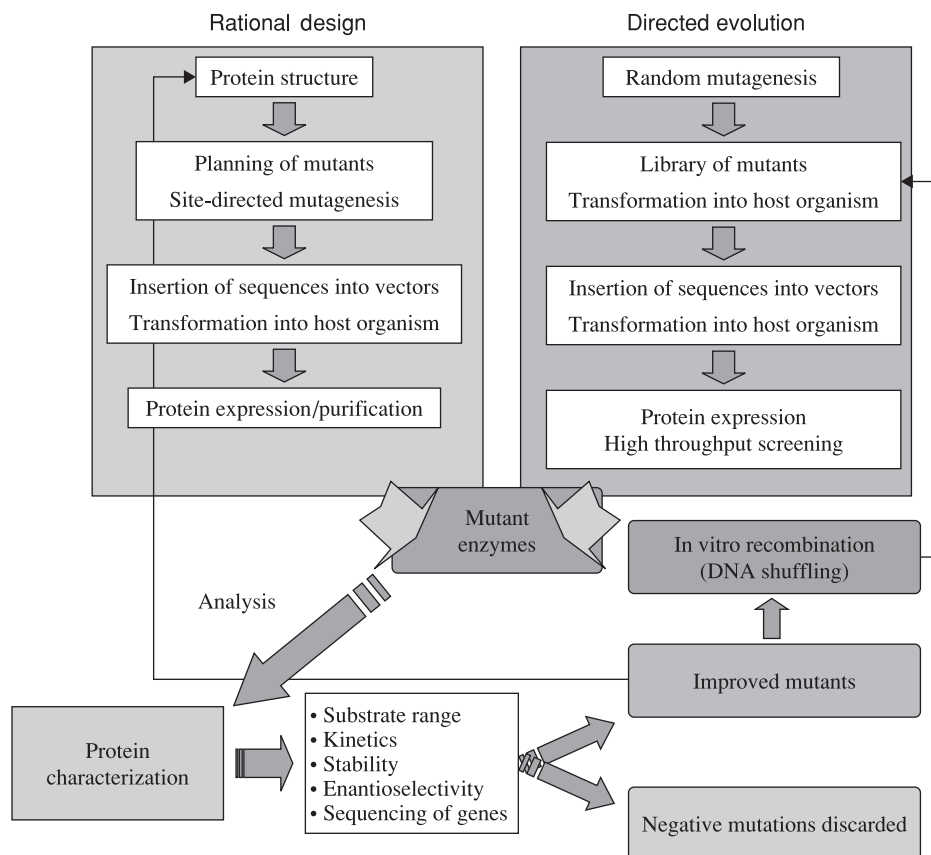
The rapid development of recombinant DNA technology since the early 1980s has changed the emphasis of a classical enzyme purification work. For example, epitope tagging is a recombinant DNA method for inserting a specific protein sequence (affinity tag) into the protein of interest (Terpe 2003). This allows the expressed tagged protein to be purified by affinity interactions with a ligand that selectively binds to the affinity tag. Examples of affinity tags and their respective ligands used for protein and enzyme purification are shown in Table 7.7.

ENZYME ENGINEERING

Another extremely promising area of enzyme technology is enzyme engineering. New enzyme structures may be designed and produced in order to improve existing ones or create new activities. Over the past two decades, with the advent of protein engineering, molecular biotechnology has permitted not only the improvement of the properties of these isolated proteins, but also the construction of 'altered versions' of these 'naturally occurring' proteins with novel or 'tailor-made' properties (Ryu

Table 7.7. Adsorbents and Elution Conditions of Affinity Tags

Affinity Tag	Matrix	Elution Condition
Poly-His	Ni^{2+}-NTA	Imidazole 20–250 mM or low pH
FLAG	Anti-FLAG monoclonal antibody	pH 3.0 or 2–5 mM EDTA
Strep-tag II	Strep-Tactin (modified streptavidin)	2.5 mM desthiobiotin
c-myc	Monoclonal antibody	Low pH
S	S-fragment of RNaseA	3 M guanidine thiocyanate, 0.2 M citrate pH 2, 3 M magnesium chloride
Calmodulin-binding peptide	Calmodulin	EGTA or EGTA with 1 M NaCl
Cellulose-binding domain	Cellulose	Guanidine HCl or urea > 4 M
Glutathione *S*-transferase	Glutathione	5–10 mM reduced glutathione

Figure 7.16. Comparison of rational design and directed evolution.


TAILOR-MADE ENZYMES BY PROTEIN ENGINEERING

There are two main intervention approaches for the construction of tailor-made enzymes: rational design and directed evolution (Chen 2001, Schmidt et al. 2009; Fig. 7.16).

Rational design takes advantage of knowledge of the three-dimensional structure of the enzyme, as well as structure/function and sequence information to predict, in a 'rational/logical' way, sites on the enzyme that when altered would endow the enzyme with the desired properties (Craik et al. 1985, Wells et al. 1987, Carter et al. 1989, Scrutton et al. 1990, Cedrone et al. 2000). Once the crucial amino acids are identified, site-directed mutagenesis is applied and the expressed mutants are screened for the desired properties. It is clear that protein engineering by rational design requires prior knowledge of the 'hot spots' on the enzyme. Directed evolution (or molecular evolution) does not require such prior sequence or three-dimensional structure knowledge, as it usually employs random-mutagenesis protocols to engineer enzymes that are subsequently screened for the desired properties (Tao and Cornish 2002, Dalby 2003,

and Nam 2000, Gerlt and Babbitt 2009, Tracewell and Arnold 2009).

Jaeger and Eggert 2004, Jestin and Kaminski 2004, Williams et al. 2004). However, both approaches require efficient expression as well as sensitive detection systems for the protein of interest (Kotzia et al. 2006). During the selection process, the mutations that have a positive effect are selected and identified. Usually, repeated rounds of mutagenesis are applied until enzymes with the desired properties are constructed. For example, it took four rounds of random mutagenesis and DNA shuffling of *Drosophila melanogaster* 2′-deoxynucleoside kinase, followed by FACS analysis, in order to yield an orthogonal ddT kinase with a 6-fold higher activity for the nucleoside analogue and a 20-fold k_{cat}/K_m preference for ddT over thymidine, an overall 10,000-fold change in substrate specificity (Liu et al. 2009b).

Usually, a combination of both methods is employed by the construction of combinatorial libraries of variants, using random mutagenesis on selected (by rational design) areas of the parental 'wild-type' protein (typically, binding surfaces or specific amino acids; Altamirano et al. 2000, Arnold 2001, Saven 2002, Johannes and Zhao 2006). For example, Park et al. rationally manipulated several active site loops in the ab/ba metallohydrolase scaffold of glyoxalase II through amino acid insertion, deletion, and substitution, and then used directed evolution to introduce random point-mutations to fine-tune the enzyme

activity (Park et al. 2006). The resulting enzyme completely lost its original activity and instead showed β-lactamase activity.

The industrial applications of enzymes as biocatalysts are numerous. Recent advances in genetic engineering have made possible the construction of enzymes with enhanced or altered properties (change of enzyme/cofactor specificity and enantios-electivity, altered thermostability, increased activity) to satisfy the ever-increasing needs of the industry for more efficient catalysts (Bornscheuer and Pohl 2001, Zaks 2001, Jaeger and Eggert 2004, Chaput et al. 2008, Zeng et al. 2009).

RATIONAL ENZYME DESIGN

The rational protein design approach is mainly used for the identification and evaluation of functionally important residues or sites in proteins. Although the protein sequence contains all the information required for protein folding and functions, to-day's state of technology does not allow for efficient protein design by simple knowledge of the amino acid sequence alone. For example, there are 10^{325} ways of rearranging amino acids in a 250-amino-acid-long protein, and prediction of the number of changes required to achieve a desired effect is an obstacle that initially appears impossible. For this reason, a successful rational design cycle requires substantial planning and could be repeated several times before the desired result is achieved. A rational protein design cycle requires the following:

1. Knowledge of the amino acid sequence of the enzyme of interest and availability of an expression system that allows for the production of active enzyme. Isolation and characterisation (annotation) of cDNAs encoding proteins with novel or pre-observed properties has been significantly facilitated by advances in genomics (Schena et al. 1995, Zweiger and Scott 1997, Schena et al. 1998, Carbone 2009) and proteomics (Anderson and Anderson 1998, Anderson et al. 2000, Steiner and Anderson 2000, Xie et al. 2009) and is increasing rapidly. These cDNA sequences are stored in gene (NCBI) and protein databanks (UniProtKB/Swiss-Prot; Release 57.12 of 15 Dec 09 of UniProtKB/Swiss-Prot contains 513,77 protein sequence entries; Apweiler et al. 2004, The UniProt Consortium 2008). However, before the protein design cycle begins, a protein expression system has to be established. Introduction of the cDNA encoding the protein of interest into a suitable expression vector/host cell system is nowadays a standard procedure (see above).
2. Structure/function analysis of the initial protein sequence and determination of the required amino acids changes. As mentioned before, the enzyme engineering process could be repeated several times until the desired result is obtained. Therefore, each cycle ends where the next begins. Although, we cannot accurately predict the conformation of a given protein by knowledge of its amino acid sequence, the amino acid sequence can provide significant information. Initial screening should therefore involve sequence comparison analysis of the original protein sequence to other sequence homologous proteins with

potentially similar functions by utilising current bioinformatics tools (Andrade and Sander 1997, Fenyo and Beavis 2002, Nam et al. 2009, Yen et al. 2009, Zhang et al. 2009a, 2009b). Areas of conserved or non-conserved amino acids residues can be located within the protein and could possibly provide valuable information, concerning the identification of binding and catalytic residues. Additionally, such methods could also reveal information pertinent to the three-dimensional structure of the protein.

3. Availability of functional assays for identification of changes in the properties of the protein. This is probably the most basic requirement for efficient rational protein design. The expressed protein has to be produced in a bioactive form and characterised for size, function and stability in order to build a baseline comparison platform for the ensuing protein mutants. The functional assays should have the required sensitivity and accuracy to detect the desired changes in the protein's properties.
4. Availability of the three-dimensional structure of the protein or capability of producing a reasonably accurate three-dimensional model by computer modelling techniques. The structures of thousands of proteins have been solved by various crystallographic techniques (X-ray diffraction, NMR spectroscopy) and are available in protein structure databanks. Current bioinformatics tools and elaborate molecular modeling software (Wilkins et al. 1999, Gasteiger et al. 2003, Guex et al. 2009) permit the accurate depiction of these structures and allow the manipulation of the aminoacid sequence. For example, they are able to predict, with significant accuracy, the consequences of a single aminoacid substitution on the conformation, electrostatic or hydrophobic potential of the protein (Guex and Peitsch 1997, Gasteiger et al. 2003, Schwede et al. 2003). Additionally, protein–ligand interactions can, in some cases, be successfully simulated, which is especially important in the identification of functionally important residues in enzyme–cofactor/substrate interactions (Saxena et al. 2009). Finally, in allosteric regulation, the induced conformational changes are very difficult to predict. In last few years, studies on the computational modelling of allostery have also began (Kidd et al. 2009).

Where the three-dimensional structure of the protein of interest is not available, computer modelling methods (homology modelling, fold recognition using threading and ab initio prediction) allow for the construction of putative models based on known structures of homologous proteins (Schwede et al. 2003, Kopp and Schwede 2004, Jaroszewski 2009, Qu et al. 2009). Additionally, comparison with proteins having homologous three-dimensional structure or structural motifs could provide clues as to the function of the protein and the location of functionally important sites. Even if the protein of interest shows no homology to any other known protein, current amino acid sequence analysis software could provide putative tertiary structural models. A generalised approach to predict protein structure is shown in Figure 7.17.
Figure 7.17. A generalised schematic for the prediction of protein three-dimensional structure.

5. Genetic manipulation of the wild-type nucleotide sequence. A combination of previously published experimental literature and sequence/structure analysis information is usually necessary for the identification of functionally important sites in the protein. Once an adequate three-dimensional structural model of the protein of interest has been constructed, manipulation of the gene of interest is necessary for the construction of mutants. Polymerase chain reaction (PCR) mutagenesis is the basic tool for the genetic manipulation of the nucleotide sequences. The genetically redesigned proteins are engineered by the following:

a. Site-directed mutagenesis: alteration of specific amino acid residues. There are a number of experimental approaches designed for this purpose. The basic principle involves the use of synthetic oligonucleotides (oligonucleotide-directed mutagenesis) that are complementary to the cloned gene of interest but contain a single (or sometimes multiple) mismatched base(s) (Balland et al. 1985, Garvey and Matthews 1990, Wagner and Benkovic 1990). The cloned gene is either carried by a single-stranded vector (M13 oligonucleotide-directed mutagenesis) or a plasmid that is later denatured by alkali (plasmid DNA oligonucleotide-directed mutagenesis) or heat (PCR-amplified oligonucleotide-directed mutagenesis) in order for the mismatched oligonucleotide to anneal.

The latter then serves as a primer for DNA synthesis catalysed by externally added DNA polymerase for the creation of a copy of the entire vector, carrying, however, a mutated base. PCR mutagenesis is the most frequently used mutagenesis method (Fig. 7.18). For example, substitution of specific amino acid positions by site-directed mutagenesis (S67D/H68D) successfully converted the coenzyme specificity of the short-chain carbonyl reductase from NADP(H) to NAD(H) as well as the product enantioselectivity without disturbing enzyme stability (Zhang et al. 2009). In another example, engineering of the maize GSTF1–1 by mutating selected G-site residues resulted in substantial changes in the pH-dependence of kinetic parameters of the enzyme (Labrou et al. 2004a). Mutation of a key residue in the H-site of the same enzyme (Ile118Phe) led to a fourfold improved specificity of the enzyme towards the herbicide alachlor (Labrou et al. 2005).

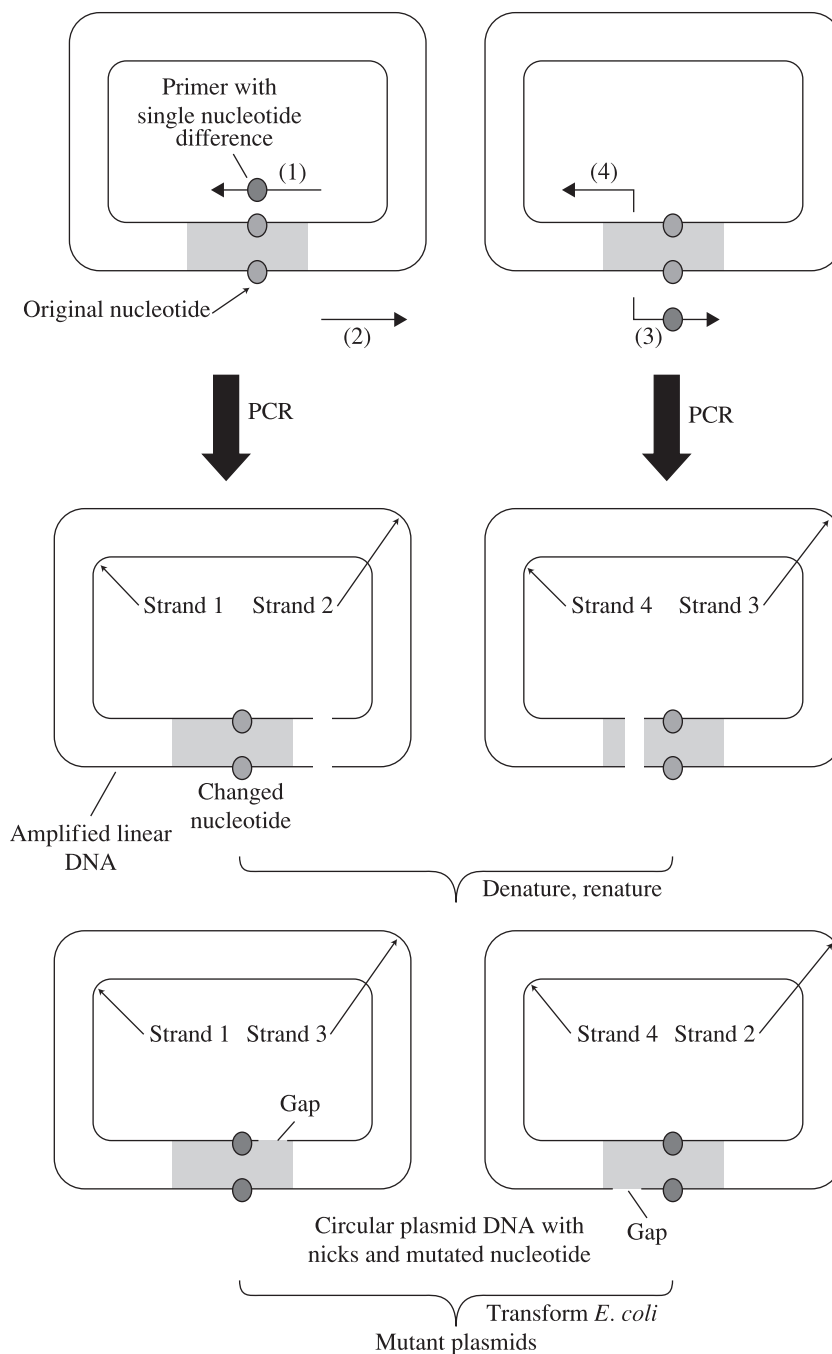
So far, substitution of a specific amino acid by another has been limited by the availability of only 20 naturally occurring amino acids. However, it is chemically possible to construct hundreds of designer-made amino acids. Incorporation of these novel protein building blocks could help shed new light into the cellular and protein functions (Wang and Schultz 2002, Chin et al. 2003, Deiters et al. 2003, Arnold 2009).


Figure 7.18. PCR oligonucleotide-directed mutagenesis. Two sets of primers are used for the amplification of the double-stranded plasmid DNA. The primers are positioned as shown and only one contains the desired base change. After the initial PCR step, the amplified PCR products are mixed together, denatured and renatured to form, along with the original amplified linear DNA, nicked circular plasmids containing the mutations. Upon transformation into *E. coli*, the nicked are repaired by host cell enzymes and the circular plasmids can be maintained.

b. Construction of deletion mutants: deletion of specified areas within or at the 5′/3′ ends (truncation mutants) of the gene.

c. Construction of insertion/fusion mutants: insertion of a functionally/structurally important epitope or fusion to another protein fragment.
   There are numerous examples of fusion proteins designed to facilitate protein expression and purification, display of proteins on surfaces of cells or phages, cellular localisation, metabolic engineering as well as protein–protein interaction studies (Nixon et al. 1998).

d. Domain swapping: exchanging of protein domains between homologous or heterologous proteins.
   For example, exchange of a homologous region between *Agrobacterium tumefaciens* β-glucosidase (optimum at pH 7.2–7.4 and 60°C) and *Cellvibrio gilvus* β-glucosidase (optimum at pH 6.2–6.4 and 35°C) resulted in a hybrid enzyme with optimal activity at pH 6.6–7.0 and 45–50°C (Singh et al. 1995). Also, domain swapping was used to clarify the control of electron transfer in nitric-oxide synthases (Nishida and Ortiz de Montellano 2001). In another example, domain swapping was observed in the structurally unrelated capsid of a rice yellow mottle virus, a member of the plant icosahedral virus group, where it was demonstrated to increase stability of the viral particle (Qu et al. 2000).

Although site-directed mutagenesis is widely used, it is not always feasible due to the limited knowledge of protein structure–function relationship and the approximate nature of computer-graphic modelling. In addition, rational design approaches can fail due to unexpected influences exerted by the substitution of one or more amino acid residues (Cherry and Fidantsef 2003, Johannes and Zhao 2006). Irrational approaches can therefore be preferable alternatives to direct the evolution of enzymes with highly specialised traits (Hibbert and Dalby 2005, Chatterjee and Yuan 2006, Johannes and Zhao 2006).

DIRECTED ENZYME EVOLUTION

Directed evolution by DNA recombination can be described as a mature technology for accelerating protein evolution. Evolution is a powerful algorithm with proven ability to alter enzyme function and especially to 'tune' enzyme properties (Cherry and Fidantsef 2003, Williams et al. 2004, Hibbert and Dalby 2005, Roodveldt et al. 2005, Chatterjee and Yuan 2006). The methods of directed evolution use the process of natural selection but in a directed way (Altreuter and Clark 1999, Kaur and Sharma 2006, Wong et al. 2006, Glasner et al. 2007, Gerlt and Babbitt 2009, Turner 2009). The major step in a typical directed enzyme evolution experiment is first to make a set of mutants and then to find the best variants through a high-throughput selection or screening procedure (Kotzia et al. 2006). The process can be iterative, so that a 'generation' of molecules can be created in a few weeks or even in a few days, with large numbers of progeny subjected to selective pressures not encountered in nature (Arnold 2001, Williams et al. 2004).

There are many methods to create combinatorial libraries, using directed evolution (Labrou 2010). Some of these are random mutagenesis using mainly error-prone PCR (Ke and Madison 1997, Cirino et al. 2003), DNA shuffling (Stemmer 1994, Crameri et al. 1998, Baik et al. 2003, Bessler et al. 2003, Dixon et al. 2003, Wada et al. 2003), StEP (staggered extension process; Zhao et al. 1998, Aguinaldo and Arnold 2003), RPR (random-priming in vitro recombination; Shao et al. 1998, Aguinaldo and Arnold 2003), incremental truncation for the creation of hybrid enzymes (ITCHY; Lutz et al. 2001), RACHITT (random chimeragenesis on transient templates; Coco et al. 2001, Coco 2003), ISM (iterative saturation mutagenesis; Reetz 2007), GSSM (gene site saturation mutagenesis; DeSantis et al. 2003, Dumon et al. 2008), PDLGO (protein domain library generation by overlap extension; Gratz and Jose 2008) and DuARCheM (dual approach to random chemical mutagenesis; Mohan and Banerjee 2008). The most frequently used methods for DNA shuffling are shown in Figure 7.19.

Currently, directed evolution has gained considerable attention as a commercially important strategy for rapid design of molecules with properties tailored for the biotechnological and pharmaceutical market. Over the past four years, DNA family shuffling has been successfully used to improve enzymes of industrial and therapeutic interest (Kurtzman et al. 2001, Chiang 2004, Dai and Copley 2004, Yuan et al. 2005). For example, by applying the DNA family shuffling approach, the catalytic properties of cytochrome P450 enzymes were further extended in the chimeric progeny to include a new range of blue colour formations. Therefore, it may be possible to direct the new enzymes towards the production of new dyes (Rosic 2009).

IMMOBILISED ENZYMES

The term 'immobilised enzymes' describes enzymes physically confined, localised in a certain region of space or attached on a support matrix (Abdul 1993). The main advantages of enzyme immobilisation are listed in Table 7.8.

There are at least four main areas in which immobilised enzymes may find applications, that is industrial, environmental, analytical and chemotherapeutic (Powell 1984, Liang et al. 2000). Environmental applications include waste water treatment and the degradation of chemical pollutants of industrial and agricultural origin (Dravis et al. 2001). Analytical applications include biosensors. Biosensors are analytical devices, which have a biological recognition mechanism (most commonly enzyme) that transduce it into a signal, usually electrical, and can be detected by using a suitable detector (Phadke 1992). Immobilised enzymes, usually encapsulated, are also being used for their possible chemotherapeutic applications in replacing enzymes that are absent from individuals with certain genetic disorders (DeYoung 1989).

METHODS FOR IMMOBILISATION

There are a number of ways in which an enzyme may be immobilised: adsorption, covalent coupling, cross-linking, matrix
Figure 7.19. A schematic representation of the most frequently used methods for DNA shuffling.

entrapment or encapsulation (Podgornik and Tennikova 2002; Fig. 7.20). These methods will be discussed in the following sections.

Adsorption

Adsorption is the simplest method and involves reversible interactions between the enzyme and the support material (Fig. 7.20A). The driving force causing adsorption is usually the formation of several non-covalent bonds such as salt links,

Table 7.8. Advantages of Immobilised Enzymes

1. Repetitive use of a single batch of enzymes.
2. Immobilisation can improve enzyme's stability by restricting the unfolding of the protein.
3. Product is not contaminated with the enzyme. This is very important in the food and pharmaceutical industries.
4. The reaction is controlled rapidly by removing the enzyme from the reaction solution (or vice versa).

van der Waals, hydrophobic and hydrogen bonding (Calleri et al. 2004). The methodology is easy to carry out and can be applied to a wide range of support matrices such as alumina, bentonite, cellulose, anion and cation exchange resins, glass, hydroxyapatite, kaolinite, etc. The procedure consists of mixing together the enzyme and a support under suitable conditions of pH, ionic strength, temperature, etc. The most significant advantages of this method are (i) absence of chemicals resulting to a little damage to enzyme and (ii) reversibility, which allows regeneration with fresh enzyme. The main disadvantage of the method is the leakage of the enzyme from the support under many conditions of changes in the pH, temperature and ionic strength. Another disadvantage is the non-specific, adsorption of other proteins or other substances to the support. This may modify the properties of the support or of the immobilised enzyme.

Covalent Coupling

The covalent coupling method is achieved by the formation of a covalent bond between the enzyme and the support

**Figure 7.20.** Representation of the methods by which an enzyme may be immobilised: adsorption, covalent coupling, cross-linking, matrix entrapment and encapsulation.

acted' during the covalent coupling and reduces the occurrence of binding in unproductive conformations.

Various types of beaded supports have been used successfully as for example, natural polymers (e.g. agarose, dextran and cellulose), synthetic polymers (e.g. polyacrylamide, polyacryloyl trihydroxymethylacrylamide, polymethacrylate), inorganic (e.g. silica, metal oxides and controlled pore glass) and microporous flat membrane (Calleri et al. 2004).

The immobilisation procedure consists of three steps (Calleri et al. 2004): (i) activation of the support, (ii) coupling of ligand and (iii) blocking of residual functional groups in the matrix. The choice of coupling chemistry depends on the enzyme to be immobilised and its stability. A number of methods are available in the literature for efficient immobilisation of enzyme through a chosen particular functional side chain's group by employing glutaraldehyde, oxirane, cyanogen bromide, 1,1-carbonyldiimidazole, cyanuric chloride, trialkoxysilane to derivatise glass, etc. Some of them are illustrated in Figure 7.21.

Cross-linking

This type of immobilisation is achieved by cross-linking the enzymes to each other to form complex structures as shown in Figure 7.20C. It is therefore a support-free method and less costly than covalent linkage. Methods of cross-linking involve covalent bond formation between the enzymes using bi- or multifunctional reagent. Cross-linking is frequently carried out using glutaraldehyde, which is of low cost and available in industrial quantities. To minimise close proximity problems associated with the cross-linking of a single enzyme, albumin and gelatin are usually used to provide additional protein molecules as spacers (Podgornik and Tennikova 2002).

Entrapment and Encapsulation

In the immobilisation by entrapment, the enzyme molecules are free in solution, but restricted in movement by the lattice structure of the gel (Fig. 7.20D; Balabushevich et al. 2004). The entrapment method of immobilisation is based on the localisation of an enzyme within the lattice of a polymer matrix or membrane (Podgornik and Tennikova 2002). It is done in such a way as to retain protein while allowing penetration of substrate. Entrapment can be achieved by mixing an enzyme with chemical monomers that are then polymerised to form a cross-linked polymeric network, trapping the enzyme in the interstitial spaces of lattice. Many materials have been used, such as alginate, agarose, gelatin, polystyrene and polyacrylamide. As an example of this latter method, the enzymes' surface lysine residues may be derivatised by reaction with acryloyl chloride ($CH_2 = CH–CO–Cl$) to give the acryloyl amides. This product may then be copolymerised and cross-linked with acrylamide ($CH_2 = CH–CO–NH_2$) and bisacrylamide ($H_2N–CO–CH = CH–CH = CH–CO–NH_2$) to form a gel.

Encapsulation of enzymes can be achieved by enveloping the biological components within various forms of semipermeable

(Fig. 7.20B). The binding is very strong and therefore little leakage of enzyme from the support occurs (Calleri et al. 2004). The bond is formed between reactive electrophile groups present on the support and nucleophile side chains on the surface of the enzyme. These side-chains are usually the amino group ($–NH_2$) of lysine, the imidazole group of histidine, the hydroxyl group ($–OH$) of serine and threonine, and the sulfydryl group ($–SH$) of cysteine. Lysine residues are found to be the most generally useful groups for covalent bonding of enzymes to insoluble supports due to their widespread surface exposure and high reactivity, especially in slightly alkaline solutions.

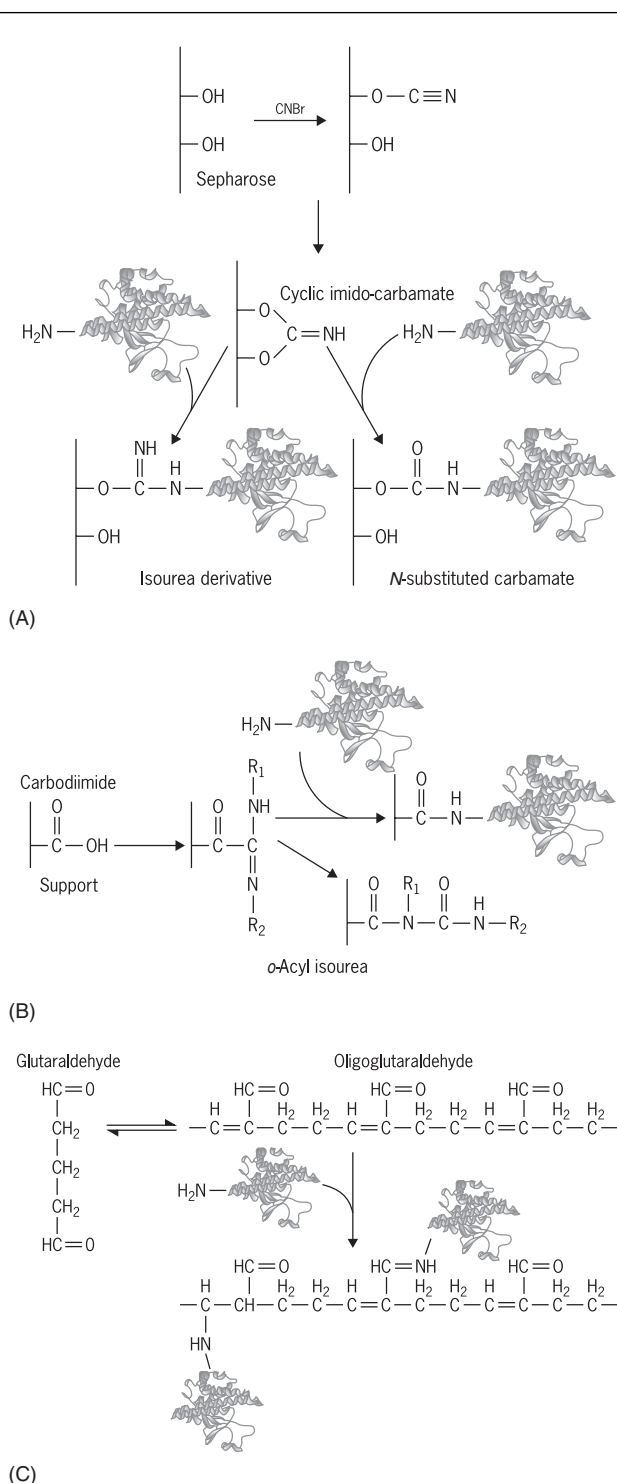
It is important that the amino acids essential to the catalytic activity of the enzyme are not involved in the covalent linkage to the support (Dravis et al. 2001). This may be difficult to achieve, and enzymes immobilised in this fashion generally lose activity upon immobilisation. This problem may be prevented if the enzyme is immobilised in the presence of saturating concentrations of substrate, product or a competitive inhibitor to protect active site residues. This ensures that the active site remains 'unre-


Figure 7.21. Commonly used methods for the covalent immobilisation of enzymes. (**A**) Activation of hydroxyl support by cyanogen bromide. (**B**) Carbodiimides may be used to attach amino groups on the enzyme to carboxylate groups on the support or carboxylate groups on the enzyme to amino groups on the support. (**C**) Glutaraldehyde is used to cross-link enzymes or link them to supports. The product of the condensation of enzyme and glutaraldehyde may be stabilised against dissociation by reduction with sodium borohydride.

membranes as shown in Figure 7.20E. Encapsulation is most frequently carried out using nylon and cellulose nitrate to construct microcapsules varying from 10 to 100 μM. In general, entrapment methods have found more application on the immobilisation of cells.

NEW APPROACHES FOR ORIENTED ENZYME IMMOBILISATION: THE DEVELOPMENT OF ENZYME ARRAYS

With the completion of several genome projects, attention has turned to the elucidation of functional activities of the encoded proteins. Because of the enormous number of newly discovered open reading frames, progress in the analysis of the corresponding proteins depends on the ability to perform characterisation in a parallel and high throughput format (Cahill and Nordhoff 2003). This typically involves construction of protein arrays based on recombinant proteins. Such arrays are then analysed for their enzymatic activities and the ability to interact with other proteins or small molecules, etc. The development of enzyme array technology is hindered by the complexity of protein molecules. The tremendous variability in the nature of enzymes and consequently in the requirement for their detection and identification makes the development of protein chips a particularly challenging task. Additionally, enzyme molecules must be immobilised on a matrix in a way that they preserve their native structures and are accessible to their targets (Cutler 2003). The immobilisation chemistry must be compatible with preserving enzyme molecules in native states. This requires good control of local molecular environments of the immobilised enzyme molecule (Yeo et al. 2004). There is one major barrier in enzyme microarray development: the immobilisation chemistry has to be such that it preserves the enzyme in native state and with optimal orientation for substrate interaction. This problem may be solved by the recently developed in vitro protein ligation methodology. Central to this method is the ability of certain protein domains (inteins) to excise themselves from a precursor protein (Lue et al. 2004). In a simplified intein expression system, a thiol reagent induces cleavage of the intein–extein bond, leaving a reactive thioester group on the C-terminus of the protein of interest. This group can then be used to couple essentially any polypeptide with an N-terminal cysteine to the thioester tagged protein by restoring the peptide bond. In another methodology, optimal orientation is based on the unique ability of protein prenyl-transferases to recognise short but highly specific C-terminal protein sequences (Cys–A–A–X–), as shown in Figure 7.22. The enzyme accepts a spectrum of phosphoisoprenoid analogues while displaying a very strict specificity for the protein substrate. This feature is explored for protein derivatisation. Several types of pyrophosphates (biotin analogues, photoreactive aside and benzophenone analogues; Fig. 7.22) can be covalently attached to the protein tagged with the Cys-A-A-X motif. After modification, the protein can be immobilised directly either reversibly through biotin–avidin interaction on avidin modified support or covalently through the photoreactive group on several supports.
Figure 7.22. Principal scheme of using CAAX-tagged proteins for covalent modification with prenyl transferases.

ENZYME UTILISATION IN INDUSTRY

Enzymes offer potential for many exciting applications in industry. Some important industrial enzymes and their sources are listed in Table 7.9. In addition to the industrial enzymes listed above, a number of enzyme products have been approved for therapeutic use. Examples include tissue plasminogen activator and streptokinase for cardiovascular disease, adenosine deaminase for the rare severe combined immunodeficiency disease, β-glucocerebrosidase for Type 1 Gaucher disease, L-asparaginase for the treatment of acute lymphoblastic leukemia, DNAse for the treatment of cystic fibrosis and neuraminidase which is being targeted for the treatment of influenza (Cutler 2003).

There are also thousands of enzyme products used in small amounts for research and development in routine laboratory practice and others that are used in clinical laboratory assays. This group also includes a number of DNA- and RNA-modifying enzymes (DNA and RNA polymerase, DNA ligase, restriction endonucleases, reverse transcriptase, etc.), which led to the de-velopment of molecular biology methods and were a foundation for the biotechnology industry (Yeo et al. 2004). The clever application of one thermostable DNA polymerase led to the PCR and this has since blossomed into numerous clinical, forensic and academic embodiments. Along with the commercial success of these enzyme products, other enzyme products are currently in commercial development.

Another important field of application of enzymes is in metabolic engineering. Metabolic engineering is a new approach involving the targeted and purposeful manipulation of the metabolic pathways of an organism, aiming at improving the quality and yields of commercially important compounds. It typically involves alteration of cellular activities by manipulation of the enzymatic functions of the cell using recombinant DNA and other genetic techniques. For example, the combination of rational pathway engineering and directed evolution has been successfully applied to optimise the pathways for the production of isoprenoids such as carotenoids (Schmidt-Dannert et al. 2000, Umeno and Arnold 2004).

Table 7.9. Some Important Industrial Enzymes and Their Sources

Enzyme	EC Number	Source	Industrial Use
Rennet	3.4.23.4	Abomasum	Cheese
α-Amylase	3.2.1.1	Malted barley, *Bacillus, Aspergillus*	Brewing, baking
α-Amylase	3.2.1.2	Malted barley, *Bacillus*	Brewing
Bromelain	3.4.22.4	Pineapple latex	Brewing
Catalase	1.11.1.6	Liver, *Aspergillus*	Food
Penicillin amidase	3.5.1.11	*Bacillus*	Pharmaceutical
Lipoxygenase	1.13.11.12	Soybeans	Food
Ficin	3.4.22.3	Fig latex	Food
Pectinase	3.2.1.15	*Aspergillus*	Drinks
Invertase	3.2.1.26	*Saccharomyces*	Confectionery
Pectin lyase	4.2.2.10	*Aspergillus*	Drinks
Cellulase	3.2.1.4	*Trichoderma*	Waste
Chymotrypsin	3.4.21.1	Pancreas	Leather
Lipase	3.1.1.3	Pancreas, *Rhizopus, Candida*	Food
Trypsin	3.4.21.4	Pancreas	Leather
α-Glucanase	3.2.1.6	Malted barley	Brewing
Papain	3.4.22.2	Pawpaw latex	Meat
Asparaginase	3.5.1.1	*Erwinia chrisanthemy, Erwinia carotovora, Escherichia coli*	Human health
Glucose isomerase	5.3.1.5	*Bacillus*	Fructose syrup
Protease	3.4.21.14	*Bacillus*	Detergent
Aminoacylase	3.5.1.14	*Aspergillus*	Pharmaceutical
Raffinase	3.2.1.22	*Saccharomyces*	Food
Glucose oxidase	1.1.3.4	*Aspergillus*	Food
Dextranase	3.2.1.11	*Penicillium*	Food
Lactase	3.2.1.23	*Aspergillus*	Dairy
Glucoamylase	3.2.1.3	*Aspergillus*	Starch
Pullulanase	3.2.1.41	*Klebsiella*	Starch
Raffinase	3.2.1.22	*Mortierella*	Food
Lactase	3.2.1.23	*Kluyveromyces*	Dairy

ENZYMES INVOLVED IN XENOBIOTIC METABOLISM AND BIOCHEMICAL INDIVIDUALITY

The term xenobiotic metabolism refers to the set of metabolic pathways that chemically modify xenobiotics, which are compounds foreign to an organism's normal biochemistry, such as drugs and poisons. The term biochemical individuality of xenobiotic metabolism refers to variability in xenobiotic metabolism and drug responsiveness among different people. Biochemical individuality is a significant factor that can improve public health, drug therapy, nutrition and health impacts such as cancer, diabetes 2 and cardiovascular disease.

Most xenobiotics are lipophilic and able to bind to lipid membranes and be transported in the blood (Hodgson 2004). The enzymes that are involved in xenobiotic metabolism (Table 7.10) comprise one of the first defense mechanism against environmental carcinogens and xenobiotic compounds (Zhang et al. 2009a). Xenobiotic metabolism follows mainly three phases (I, II, III). In Phase I, the original compound obtain increased hydrophilicity and constitute an adequate substrate for phase II enzymes, by the introduction of a polar reactive group (–OH,

$-NH_2$, –SH or –COOH). In Phase II, the products of Phase I can be conjugated to substrates such as GSH, which result in a significant increase of water solubility of xenobiotic, promoting its excretion (Hodgson 2004). The ATP-dependent transporters that facilitate the movement of the polar conjugates (by phase I and II) across biological membranes and their excretion from the cell constitute Phase III proteins (Josephy and Mannervik 2006). In general, the enzymes that are involved in xenobiotic metabolism are genetically polymorphic, affecting the individual delicacy to environmental pollutants (Zhang et al. 2009a).

PHASE I

Human cytochrome P450, is one of the most important enzymes that takes part in xenobiotic metabolism; therefore, its genetic polymorphisms have been studied in depth. For example, P450 2A6 (CYP2A6) catalyses nicotine oxidation, and it has been found to have inter-individual and inter-ethnic variability. Genetic polymorphisms of this gene impact smoking behaviour (Xu et al. 2002). Another example of genetic polymorphism's impact of this enzyme came from Siraj et al., who suggested that CYP1A1 phenotype AA showed association with increased

Table 7.10. The Main Enzymes Involved in Xenobiotic Metabolism

	Reactions
Phase I enzymes	
Cytochrome P450 (CYPs)	Epoxidation/hydroxylation
	N-, O-, S-dealkylation
	N-, S-, P-oxidation
	Desulfuration
	Dehalogenation
	Azo reduction
	Nitro reduction
Flavin-containing monooxygenases (FMOs)	N-, S-, P-oxidation
	Desulfuration
Alcohol dehydrogenase	Oxidation
	Reductions
Aldehyde dehydrogenase	Oxidation
Prostaglandin synthetase co-oxidation	Dehydrogenation
	N-dealkylation
	Epoxidation/hydroxylation
	Oxidation
Molybdenum hydroxylases	Oxidation
	Reductions
Esterases and amidases	Hydrolysis
Epoxide hydrolase	Hydrolysis
Phase II enzymes	
UDP (uridine diphospho) glucuronosyl transferase (UGT)	Glucuronide conjugation
Sulfotransferases	Sulfation reaction
Sulfatases	Hydrolysis of sulfate esters
Methyltransferases	N-, O-, S-methylation,
Glutathione S-transferase	Alkyltransferase, aryltransferase, aralkyltransferase, alkenetransferase, epoxidetransferase
γ-Glutamyltranspeptidase	Hydrolysis
	Transpeptidation
N-acetyltransferase	Acetylation
Aminopeptidases	Hydrolysis of peptides
N,O-Acyltransferase	Acylation
Cysteine conjugate β-lyase	Methylation
Phase III enzymes	
MRP (multi-drug resistance – associated protein)	Transport and excretion of soluble products from phase I and II metabolic pathways
MDR (multi-drug resistance family/P-glycoprotein)	
MXR (mitoxantrone-resistance protein) efflux

risk of developing papillary thyroid cancer in Middle Eastern population (Siraj et al. 2008).

Another studied genetic polymorphic enzyme is superoxide dismutase-2 (SOD). The heterozygosity 9Val-allele of MnSOD is associated with a higher risk and severity of orofaciolingual dyskinesias (TDof) in Russian psychiatric inpatients from Siberia (Al Hadithy et al. 2010). In addition, there are several studies that have reported and showed that the 9Val/9Val genotype confer great susceptibility to tardive dyskinesia (Zhang et al. 2003, Akyol et al. 2005, Galecki et al. 2006, Hitzeroth et al. 2007). In addition, human MnSOD gene encoding alanine

(A) or valine at codon 16 (Shimoda-Matsubayashi et al. 1996) can be a risk factor for several malignancies (Iguchi et al. 2009).

PHASE II

Polymorphisms of human UGT correlate with diseases and side effects of drugs, for example the isoform UGT1A1 is associated with diseases of bilirubin metabolism (Hodgson 2004). N-Acetyltransferases (NAT) are important enzymes that participate in metabolic activation of carcinogenic aromatic and heterocyclic amines that are present in cigarette smoke (Wang

et al. 1999). An association was found between smokers with MnSOD AA genotype and prostate cancer risk, especially in case of rapid NAT1 subjects (Iguchi et al. 2009). Tamini et al. found that the AA genotype of MnSOD in women smokers have an elevated risk for breast cancer (Tamini et al. 2004).

Tobacco smoke (Lioy and Greenberg 1990) as well as smoked foods, cereals, leafy green vegetables and fossil fuels combustion by-products (Waldman et al. 1991) are the sources of exposure to polycyclic aromatic hydrocarbons (PAHs). PAHs have been considered as potential carcinogens for human (Shimada 2006). According to McCarty et al., the lack of dose–response relationship of PAHs and breast cancer may be due to genetic differences in metabolic activation and detoxification of PAHs (McCarty et al. 2009).

Phase III

The proteins of phase III are membrane transporters. These proteins seem to be significantly implicated in the absorption, distribution and discard of drugs (Rommel and Richard 2002). There are genetic polymorphisms of drug transporters, which appear to have clinical impact and have been detected in multiple clinical and in vitro studies (Maeda and Sugiyama 2008).

Enzyme Activities

D. J. H. Shyu, J. T. C. Tzen, and C. L. Jeang

INTRODUCTION

Long before human history, our ancestors, chimpanzees, might have already experienced the mild drunk feeling of drinking wine when they ate the fermented fruits that contained small amounts of alcohol. Archaeologists have also found some sculptured signs on 8000-year-old plates describing the beer-making processes. Chinese historians wrote about the lavish life of Tsou, a tyrant of Shang dynasty (around 1100 BC), who lived in a castle with wine-storing pools. All these indicated that people grasped the wine fermentation technique thousands of years ago. In the Chin dynasty (around 220 BC) China, a spicy paste or sauce made from fermentation of soybean and/or wheat was mentioned. It is now called soybean sauce.

Although people applied fermentation techniques and observed the changes from raw materials to special products, they did not realize the mechanisms that caused the changes. This mystery was uncovered by the development of biological sciences. Louis Pasteur claimed the existence and function of organisms that were responsible for the changes. In the same era, Justus Liebig observed the digestion of meat with pepsin, a substance found in stomach fluid, and proposed that a whole organism is not necessary for the process of fermentation.

In 1878, Kuhne was the first person to solve the conflict by introducing the word "enzyme," which means "in yeast" in Greek.

This word emphasizes the materials inside or secreted by the organisms to enhance the fermentation (changes of raw material). Buchner (1897) performed fermentation by using a cell-free extract from yeast of significantly high light, and these were molecules rather than lifeforms that did the work. In 1905, Harden and Young found that fermentation was accelerated by the addition of some small dialyzable molecules to the cellfree extract. The results indicated that both macromolecular and micromolecular compounds are needed. However, the nature of enzymes was not known at that time. A famous biochemist, Willstátter, was studying peroxidase for its high catalytic efficiency; since he never got enough samples, even though the reaction obviously happened, he hesitated (denied) to conclude that the enzyme was a protein. Finally, in 1926, Summer prepared crystalline urease from jack beans, analyzed the properties of the pure compound, and drew the conclusion that enzymes are proteins. In the following years, crystalline forms of some proteases were also obtained by Northrop et al. The results agreed with Summer's conclusion.

The studies on enzyme behavior were progressing in parallel. In 1894, Emil Fischer proposed a "lock and key" theory to describe the specificity and stereo relationship between an enzyme and its substrate. In 1902, Herri and Brown independently reported a saturation-type curve for enzyme reactions. They revealed an important concept in which the enzyme substrate complex was an obligate intermediate formed during the enzyme-catalyzed reaction. In 1913, Michaelis and Menten derived an equation describing quantitatively the saturation-like behavior. At the same time, Monod and others studied the kinetics of regulatory enzymes and suggested a concerted model for the enzyme reaction. In 1959, Fischer's hypothesis was slightly modified by Koshland. He proposed an induced-fit theory to describe the moment the enzyme and substrate are attached, and suggested a sequential model for the action of allosteric enzymes.

For the studies on enzyme structure, Sanger et al. were the first to announce the unveiling of the amino acid sequence of a protein, insulin. After that, the primary sequences of some hydrolases with comparatively small molecular weights, such as ribonuclease, chymotrypsin, lysozyme, and others, were defined. Twenty years later, Sanger won his second Nobel Prize for the establishment of the chain-termination reaction method for nucleotide sequencing of DNA. On the basis of this method, the deduction of the primary sequences of enzymes blossomed; to date, the primary structures of 55,410 enzymes have been deduced. Combining genetic engineering technology and modern computerized X-ray crystallography and/or Nucleai magnetic resonance (NMR), about 15,000 proteins, including 9268 proteins and 2324 enzymes, have been analyzed for their three-dimensional structures (Protein Data Bank (PDB): http://www.rcsb.org/pdb). Computer software was created, and protein engineering on enzymes with demanded properties was carried on successfully (Fang and Ford 1998, Igarashi et al. 1999, Pechkova et al. 2003, Shiau et al. 2003, Swiss-PDBViewer(spdbv): http://www.expasy.ch/spdbv/mainpage .htm, SWISSMODELserver: http://www.expasy.org/swissmod/SWISS-MODEL.htm).

FEATURES OF ENZYMES

MOST OF THE ENZYMES ARE PROTEINS

Proteins are susceptible to heat, strong acids and bases, heavy metals, and detergents. They are hydrolyzed to amino acids by heating in acidic solution and by the proteolytic action of enzymes on peptide bonds. Enzymes give positive results on typical protein tests, such as the Biuret, Millions, Hopkins-Cole, and Sakaguchi reactions. X-ray crystallographic studies revealed that there are peptide bonds between adjacent amino acid residues in proteins. The majority of the enzymes fulfill the above criterion; therefore, they are proteins in nature. However, the catalytic element of some well-known ribozymes is just RNAs in nature (Steitz and Moore 2003, Raj and Liu 2003).

CHEMICAL COMPOSITION OF ENZYMES

For many enzymes, protein is not the only component required for its full activity. On the basis of the chemical composition of enzymes, they are categorized into several groups, as follows:

1. Polypeptide, the only component, for example, lysozyme, trypsin, chymotrypsin, or papain.
2. Polypeptide plus one to two kinds of metal ions, for example, α-amylase containing Ca^{2+}, kinase containing Mg^{2+}, and superoxide dismutase having Cu^{2+} and/or Zn^{2+}.
3. Polypeptide plus a prosthetic group, for example, peroxidase containing a heme group.
4. Polypeptide plus a prosthetic group and a metal ion, for example, cytochrome oxidase $(a + a_3)$ containing a heme group and Cu^{2+}.
5. Polypeptide plus a coenzyme, for example, many dehydrogenases containing NAD^+ or $NADP^+$.
6. Combination of polypeptide, coenzyme, and a metal ion, for example, succinate dehydrogenase containing both the FAD and nonheme iron.

ENZYMES ARE SPECIFIC

In the life cycle of a unicellular organism, thousands of reactions are carried out. For the multicellular higher organisms with tissues and organs, even more kinds of reactions are progressing in every moment. Less than 1% of errors that occur in these reactions will cause accumulation of waste materials (Drake 1999), and sooner or later the organism will not be able to tolerate these accumulated waste materials. These phenomena can be explained by examining genetic diseases; for example, phenylketonuria (PKU) in humans, where the malfunction of phenylalanine hydroxylase leads to an accumulation of metabolites such as phenylalanine and phenylacetate, and others, finally causing death (Scriver 1995, Waters 2003). Therefore, enzymes catalyzing the reactions bear the responsibility for producing desired metabolites and keeping the metabolism going smoothly.

Enzymes have different types of specificities. They can be grouped into the following common types:

1. *Absolute specificity:* For example, urease (Sirko and Brodzik 2000) and carbonate anhydrase (Khalifah 2003) catalyze only the hydrolysis and cleavage of urea and carbonic acid, respectively. Those enzymes having small molecules as substrates or that work on biosynthesis pathways belong to this category.
2. *Group specificity:* For example, hexokinase prefers D-glucose, but it also acts on other hexoses (Cardenas et al. 1998).
3. *Stereo specificity:* For example, D-amino acid oxidase reacts only with D-amino acid, but not with L-amino acid; and succinate dehydrogenase reacts only with the fumarate (*trans* form), but not with maleate (*cis* form).
4. *Bond specificity:* For example, many digestive enzymes. They catalyze the hydrolysis of large molecules of food components, such as proteases, amylases, and lipases. They seem to have broad specificity in their substrates; for example, trypsin acts on all kinds of denatured proteins in the intestine, but prefers the basic amino acid residues at the *C*-terminal of the peptide bond. This broad specificity brings up an economic effect in organisms; they are not required to produce many digestive enzymes for all kinds of food components.

The following two less common types of enzyme specificity are impressive: (1) An unchiral compound, citric acid is formed by citrate synthase with the condensation of oxaloacetate and acetyl-CoA. An aconitase acts only on the moiety that comes from oxaloacetate. This phenomenon shows that, for aconitase, the citric acid acts as a chiral compound (Barry 1997). (2) If people notice the rare mutation that happens naturally, they will be impressed by the fidelity of certain enzymes, for example, amino acyltRNA synthethase (Burbaum and Schimmel 1991, Cusack 1997), RNA polymerase (Kornberg 1996), and DNA polymerase (Goodman 1997); they even correct the accidents that occur during catalyzing reactions.

Enzymes are Regulated

The catalytic activity of enzymes is changeable under different conditions. These enzymes catalyze the set steps of a metabolic pathway, and their activities are responsible for the states of cells. Intermediate metabolites serve as modulators on enzyme activity; for example, at high concentrations of adenosine diphosphate, the catalytic activity of the phosphofructokinase, pyruvate kinase, and pyruvate dehydrogenase complex are enhanced; as adenosine triphosphate becomes high, they will be inhibited. These modulators bind at allosteric sites on enzymes (Hammes 2002). The structure and mechanism of allosteric regulatory enzymes such as aspartate transcarbamylase (Cherfils et al. 1990) and ribonucleoside diphosphate reductase (Scott et al. 2001) have been well studied. However, allosteric regulation is not the only way that the enzymatic activity is influenced. Covalent modification by protein kinases (Langfort et al. 1998) and phosphatases (Luan 2003) on enzymes will cause large fluctuations

in total enzymatic activity in the metabolism pool. In addition, sophisticated tuning phenomena on glycogen phosphorylase and glycogen synthase through phosphorylation and dephosphorylation have been observed after hormone signaling (Nuttall et al. 1988, Preiss and Romeo 1994).

Enzymes are Powerful Catalysts

The compound glucose will remain in a bottle for years without any detectable changes. However, when glucose is applied in a minimal medium as the only carbon source for the growth of *Salmonella typhimurium* (or *Escherichia coli*), phosphorylation of this molecule to glucose-6-phosphate is the first chemical reaction that occurs as it enters the cells. From then on, the activated glucose not only serves as a fuel compound to be oxidized to produce chemical energy, but also goes through numerous reactions to become the carbon skeleton of various micro- and macrobiomolecules. To obtain each end product, multiple steps have to be carried out. It may take less than 30 minutes for a generation to go through all the reactions. Only the existence of enzymes guarantees this quick utilization and disappearance of glucose.

ENZYMES AND ACTIVATION ENERGY

Enzymes Lower the Activation Energy

Enzymes are mostly protein catalysts; except for the presence of a group of ribonucleic acid-mediated reactions, they are responsible for the chemical reactions of metabolism in cells. For the catalysis of a reaction, the reactants involved in this reaction all require sufficient energy to cross the potential energy barrier, the activation energy (E_A), for the breakage of the chemical bonds and the start of the reaction. Few have enough energy to cross the reaction energy barrier until the reaction catalyst (the enzyme) forms a transition state with the reactants to lower the E_A (Fig. 8.1). Thus, the enzyme lowers the barrier that usually prevents the chemical reaction from occurring and facilitates the reaction proceeding at a faster rate to approach equilibrium. The substrates (the reactants), which are specific for the enzyme involved in the reaction, combine with enzyme to lower the E_A of the reaction. One enzyme type will combine with one specific type of substrate, that is, the active site of one particular enzyme will only fit one specific type of substrate, and this leads to the formation of and enzyme–substrate (ES) complex. Once the energy barrier is overcome, the substrate is then changed to another chemical, the product. It should be noted that the enzyme itself is not consumed or altered by the reaction, and that the overall free-energy change (ΔG) or the related equilibrium also remain constant. Only the activation energy of the uncatalyzed reaction (E_{Au}) decreases to that of the enzyme-catalyzed reaction (E_{Ac}).

One of the most important mechanisms of the enzyme function that decreases the E_A involves the initial binding of the enzyme to the substrate, reacting in the correct direction, and closing of the catalytic groups of the ES complex. The binding energy, part of the E_A, is required for the enzyme to bind to the substrate and is determined primarily by the structure complementarities
Figure 8.1. A transition state diagram, also called reaction coordinate diagram, shows the activation energy profile of the course of an enzyme-catalyzed reaction. One curve depicts the course of the reaction in the absence of the enzyme, while the other depicts the course of reaction in the presence of the enzyme that facilitates the reaction. The difference in the level of free energy between the beginning state (ground state) and the peak of the curve (transition state) is the activation energy of the reaction. The presence of enzyme lowers the activation energy (E_A) but does not change the overall free energy ($\triangle G$).

between the enzyme and the substrate. The binding energy is used to reduce the free energy of the transition-state ES complex but not to form a stable, not easily separated, complex. For a reaction to occur, the enzyme acts as a catalyst by efficiently binding to its substrate, lowering the energy barrier, and allowing the formation of product. The enzyme stabilizes the transition state of the catalyzed reaction, and the transition state is the rate-limiting state in a single-step reaction. In a two-step reaction, the step with the highest transition-state free energy is said to be the rate-limiting state. Though the reaction rate is the speed at which the reaction proceeds toward equilibrium, the speed of the reaction does not affect the equilibrium point.

How Does an Enzyme work?

An enzyme carries out the reaction by temporarily combining with its specific kind of substrate, resulting in a slight change of their structures to produce a very precise fit between the two molecules. The introduction of strains into the enzyme and substrate shapes allows more binding energy to be available for the transition state. Two models of this minor structure modification are the induced fit, in which the binding energy is used to distort the shape of the enzyme, and the induced strain, in which binding energy is used to distort the shape of the substrate. These two models, in addition to a third model, the nonproductive binding model, have been proposed to describe conformational flexibility during the transition state. The chemical bonds of the

substrate break and form new ones, resulting in the formation of new product. The newly formed product is then released from the enzyme, and the enzyme combines with another substrate for the next reaction.

ENZYME KINETICS AND MECHANISM

Regulatory Enzymes

For the efficient and precise control of metabolic pathways in cells, the enzyme, which is responsible for a specific step in a serial reaction, must be regulated.

Feedback Inhibition

In living cells, a series of chemical reactions in a metabolic pathway occurs, and the resulting product of one reaction becomes the substrate of the next reaction. Different enzymes are usually responsible for each step of catalysis. The final product of each metabolic pathway will inhibit the earlier steps in the serial reactions. This is called feedback inhibition.

Noncompetitive Inhibition

An allosteric site is a specific location on the enzyme where an allosteric regulator, a regulatory molecule that does not directly block the active site of the enzyme, can bind. When the allosteric regulator attaches to the specific site, it causes a change in the conformation of enzyme active site, and the substrate therefore will not fit into the active site of enzyme; this results in the inhibition phenomenon. The enzyme cannot catalyze the reaction, and not only the amount of final product but also the concentration of the allosteric regulator decrease. Since the allosteric regulator (the inhibitor) does not compete with the substrate for binding to the active site of enzyme, the inhibition mechanism is called noncompetitive inhibition.

Competitive Inhibition

A regulatory molecule is not the substrate of the specific enzyme but shows affinity for attaching to the active site. When it occupies the active site, the substrate cannot bind to the enzyme for the catalytic reaction, and the metabolic pathway is inhibited. Since the regulatory molecule will compete with the substrate for binding to the active site on enzyme, this inhibitory mechanism of the regulatory molecule is called competitive inhibition.

Enzyme Kinetics

During the course of an enzyme-catalyzed reaction, the plot of product formation over time (product formation profile) reveals an initial rapid increase, approximately linear, of product, and then the rate of increase decreases to zero as time passes (Fig. 8.2A). The slope of initial rate (v_i or v), also called the steady state rate, appears to be initially linear in a plot where the product concentration versus reaction time follows the
Figure 8.2. (A) Plot of progress curve during an enzyme-catalyzed reaction for product formation. **(B)** Plot of progress curves during an enzyme-catalyzed reaction for product formation with a different starting concentration of substrate. **(C)** Plot of reaction rate as a function of substrate concentration measured from slopes of lines from **(B)**.

for each substrate concentration are measured as the slope of a plot of product formation over time. A plot of initial rate as a function of substrate concentration is demonstrated as shown in Figure 8.2C. Three distinct portions of the plot will be noticed: an initial linear relationship showing first-order kinetic at low substrate concentrations; an intermediate portion showing curved linearity dependent on substrate concentration, and a final portion revealing no substrate concentration dependency, i.e., zero-order kinetic, at high substrate concentrations. The interpretation of the phenomenon can be described by the following scheme:

> The initial rate will be proportional to the ES complex concentration if the total enzyme concentration is constant and the substrate concentration varies. The concentration of the ES complex will be proportional to the substrate concentration at low substrate concentrations, and the initial rate will show a linear relationship and substrate concentration dependency. All of the enzyme will be in the ES complex form when substrate concentration is high, and the rate will depend on the rate of ES transformation into enzyme-product and the subsequent release of product. Adding more substrate will not influence the rate, so the relationship of rate versus substrate concentration will approach zero (Brown 1902).

However, a lag phase in the progress of the reaction will be noticed in coupled assays due to slow or delayed response of the detection machinery (see below). Though v can be determined at any constant concentration of substrate, it is recommended that the value of substrate concentration approaching saturation (high substrate concentration) be used so that it can approach its limiting value V_{max} with greater sensitivity and prevent errors occurring at lower substrate concentrations.

Measurement of the rate of enzyme reaction as a function of substrate concentration can provide information about the kinetic parameters that characterize the reaction. Two parameters are important for most enzymes—K_m, an approximate measurement of the tightness of binding of the substrate to the enzyme; and V_{max}, the theoretical maximum velocity of the enzyme reaction. To calculate these parameters, it is necessary to measure the enzyme reaction rates at different concentrations of substrate, using a variety of methods, and analyze the resulting data. For the study of single-substrate kinetics, one saturating concentration of substrate in combination with varying substrate concentrations can be used to investigate the initial rate (v), the catalytic constant (k_{cat}), and the specific constant (k_{cat}/K_m). For investigation of multisubstrate kinetics, however, the dependence of v on the concentration of each substrate has to be determined, one after another; that is, by measuring the initial rate at varying concentrations of one substrate with fixed concentrations of other substrates.

A large number of enzyme-catalyzed reactions can be explained by the Michaelis-Menten equation:

$$v = \frac{V_{max}[S]}{(K_m + [S])} = \frac{k_{cat}[E][S]}{(K_m + [S])},$$

where [E] and [S] are the concentrations of enzyme and substrate, respectively (Michaelis and Menten 1913). The equation describes the rapid equilibrium that is established between the reactant molecules (E and S) and the ES complex, followed by

establishment of the steady state of a reaction. When the reaction is approaching equilibrium or the substrate is depleted, the rate of product formation decreases, and the slope strays away from linearity. As is known by varying the conditions of the reaction, the kinetics of a reaction will appear linear during a time period in the early phase of the reaction, and the reaction rate is measured during this phase. When the substrate concentrations are varied, the product formation profiles will display linear substrate dependency at this phase (Fig. 8.2B). The rates

slow formation of product and release of free enzyme. It assumes that $k_2 \ll k_{-1}$ in the following equation, and K_m is the value of [S] when $v = V_{max}/2$:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P.$$
Briggs and Haldane (1924) proposed another enzyme kinetic model, called the steady state model; steady state refers to a period of time when the rate of formation of ES complex is the same as rate of formation of product and release of enzyme. The equation is commonly the same as that of Michaelis and Menten, but it does not require $k_2 \ll k_{-1}$, and $K_m = (k_{-1} + k_2)/k_1$, because [ES] now is dependent on the rate of formation of the ES complex (k_1) and the rate of dissociation of the ES complex (k_{-1} and k_2). Only under the condition that $k_2 \ll k_{-1}$ will $K_s = k_{-1}/k_1$ and be equivalent to K_m, the dissociation constant of the ES complex $\{K_s = k_{-1}/k_1 = ([E] - [ES])[S]/[ES]\}$, otherwise $K_m > K_s$.

The K_m is the substrate concentration at half of the maximum rate of enzymatic reaction, and it is equal to the substrate concentration at which half of the enzyme active sites are saturated by the substrate in the steady state. So, K_m is not a useful measure of ES binding affinity in certain conditions when K_m is not equivalent to K_s. Instead, the specific constant (k_{cat}/K_m) can be substituted as a measure of substrate binding; it represents the catalytic efficiency of the enzyme. The k_{cat}, the catalytic constant, represents conversion of the maximum number of reactant molecules to product per enzyme active site per unit time, or the number of turnover events occurring per unit time; it also represents the turnover rate whose unit is the reciprocal of time. In the Michaelis-Menten approach, the dissociation of the EP complex is slow, and the k_{cat} contribution to this rate constant will be equal to the dissociation constant. However, in the Briggs-Haldane approach, the dissociation rate of ES complex is fast, and the k_{cat} is equal to k_2. In addition, the values of k_{cat}/K_m are used not only to compare the efficiencies of different enzymes but also to compare the efficiencies of different substrates for a specified enzyme.

Deviations of expected hyperbolic reaction are occasionally found due to such factors as experimental artifacts, substrate inhibition, existence of two or more enzymes competing for the same substrate, and the cooperativity. They show nonhyperbolic behavior that cannot fit well into the Michaelis-Menten approach. For instance, a second molecule binds to the ES complex and forms an inactive ternary complex that usually occurs at high substrate concentrations and is noticed when rate values are lower than expected. It leads to breakdown of the Michaelis-Menten equation. It is not only the Michaelis-Menten plot that is changed to show a nonhyperbolic behavior; it is also the Lineweaver–Burk plot that is altered to reveal the nonlinearity of the curve (see later).

A second example of occasionally occurring nonhyperbolic reactions is the existence of more than one enzyme in a reaction that competes for the same substrate; the conditions usually are realized when crude or partially purified samples are used. Moreover, the conformational change in the enzymes may be induced by ligand binding for the regulation of their activities,

as discussed earlier in this chapter; many of these enzymes are composed of multimeric subunits and multiple ligand-binding sites in cases that do not obey the Michaelis-Menten equation. The sigmoid, instead of the hyperbolic, curve is observed; this condition, in which the binding of a ligand molecule at one site of an enzyme may influence the affinities of other sites, is known as cooperativity. The increase and decrease of affinities of enzyme binding sites are the effects of positive and negative cooperativity, respectively. The number of potential substrate binding sites on the enzymes can be quantified by the Hill coefficient, h, and the degree of cooperativity can be measured by the Hill equation (see page 164). More detailed illustrations and explanations of deviations from Michaelis-Menten behavior can be found in the literatures (Bell and Bell 1988, Cornish-Bowden 1995).

DATA PRESENTATION

Untransformed Graphics

The values of K_m and V_{max} can be determined graphically using nonlinear plots by measuring the initial rate at various substrate concentrations and then transforming them into different kinetic plots. First, the substrate stock concentration can be chosen at a reasonably high level; then, a two-fold (stringently) or five- or ten-fold (roughly) serial dilution can be made from this stock. After the data obtained has been evaluated, a Michaelis-Menten plot of rate v_i as a function of substrate concentration [S] is subsequently drawn, and the values of both K_m and V_{max} can be estimated. Through the plot, one can check if a hyperbolic curve is observed, and if the values estimated are meaningful. Both values will appear to be infinite if the range of substrate concentrations is low; on the other hand, although the value of V_{max} can be approximately estimated, that of K_m cannot be determined if the range of substrate concentrations is too high. Generally, substrate concentrations covering 20–80% of V_{max}, which corresponds to a substrate concentration of 0.25–5.0 K_m, is appreciated.

Lineweaver–Burk Plots

Though nonlinear plots are useful in determining the values of K_m and V_{max}, transformed, linearized plots are valuable in determining the kinetics of multisubstrate enzymes and the interaction between enzymes and inhibitors. One of the best known plots is the double-reciprocal or Lineweaver–Burk plot (Lineweaver and Burk 1934). Inverting both sides of the Michaelis-Menten equation gives the Lineweaver–Burk plot: $1/v = (K_m/V_{max})(1/[S]) + 1/V_{max}$ (Fig. 8.3). The equation is for a linear curve when one plots $1/v$ against $1/[S]$ with a slope of K_m/V_{max} and a y intercept of $1/V_{max}$. Thus, the kinetic values can also be determined from the slope and intercept values of the plot. However, caution should be taken due to small experimental errors that may be amplified by taking the reciprocal (the distorting effect), especially in the measurement of v values at low substrate concentrations. The problem can be solved by preparing a series of substrate concentrations evenly spaced along the $1/[S]$ axis, that
Figure 8.3. The Lineweaver–Burk double-reciprocal plot.

Figure 8.5. The Hanes–Wolff plot.

is, diluting the stock solution of substrate by two-, three-, four-, five-, ... fold (Copeland 2000).

Eadie–Hofstee Plots

The Michaelis-Menten equation can be rearranged to give $v = -K_m (v/[S]) + V_{max}$ by first multiplying both sides by $K_m + [S]$, and then dividing both sides by [S]. The plot will give a linear curve with a slope of $-K_m$ and a y intercept of v when v is plotted against $v/[S]$ (Fig. 8.4). The Eadie–Hofstee plot has the advantage of decompressing data at high substrate concentrations and being more accurate than the Lineweaver–Burk plot, but the values of v against [S] are more difficult to determine (Eadie 1942, Hofstee 1959). It also has the advantage of observing the range of v from zero to V_{max} and is the most effective plot for revealing deviations from the hyperbolic reaction when two or more components, each of which follows the Michaelis-Menten equation, although errors in v affect both coordinates (Cornish-Bowden 1996).

Hanes–Wolff Plots

The Lineweaver–Burk equation can be rearranged by multiplying both sides by [S]. This gives a linear plot $[S]/v = (1/V_{max})[S] + K_m/V_{max}$, with a slope of $1/V_{max}$, the y intercept of K_m/V_{max}, and the x intercept of $-K_m$ when $[S]/v$ is plotted as a function of [S] (Fig. 8.5). The plot is useful in obtaining kinetic values without distorting the data (Hanes 1932).

Eisenthal–Cornish-Bowden Plots (the Direct Linear Plots)

As in the Michaelis-Menten plot, pairs of rate values of v and the negative substrate concentrations [S] are applied along the y and x axis, respectively. Each pair of values is a linear curve that connects two points of values and extrapolates to pass the intersection. The location (x, y) of the point of intersection on the two-dimensional plot represents K_m and V_{max}, respectively (Fig. 8.6). The direct linear plots (Eisenthal and Cornish-Bowden

Figure 8.4. The Eadie–Hofstee plot.
Figure 8.6. The Eisenthal–Cornish-Bowden direct plot.
Figure 8.7. The Hill plot.

1974) are useful in estimating the Michaelis-Menten kinetic parameters and are the better plots for revealing deviations from the reaction behavior.

Hill Plot

The Hill equation is a quantitative analysis measuring non–Michaelis-Menten behavior of cooperativity (Hill 1910). In a case of completely cooperative binding, an enzyme contains h binding sites that are all occupied simultaneously with a dissociation constant $K = [E][S]^h/[ES_h]$, where h is the Hill coefficient, which measures the degree of cooperativity. If there is no cooperativity, $h = 1$; there is positive cooperativity when $h > 1$, negative cooperativity when $h < 1$. The rate value can be expressed as $v = V_{max}[S]^h/(K + [S]^h)$, and the Hill equation gives a linear $\log(v_i/V_{max} - v) = h\log[S] - \log K$, when $\log(v/V_{max} - v)$ is plotted as a function of $\log[S]$ with a slope of h and a y intercept of $-\log K$ (Fig. 8.7). However, the equation will show deviations from linearity when outside a limited range of substrate concentrations, that is, in the range of $[S] = K$.

FACTORS AFFECTING ENZYME ACTIVITY

As discussed earlier in this chapter, the rate of an enzymatic reaction is very sensitive to reaction conditions such as temperature, pH, ionic strength, buffer constitution, and substrate concentration. To investigate the catalytic mechanism and the efficiency of an enzyme with changes in the parameters, and to evaluate a suitable circumstance for assaying the enzyme activity, the conditions should be kept constant to allow reproducibility of data and to prevent a misleading interpretation.

Enzyme, Substrate, and Cofactor Concentrations

In general, the substrate concentration should be kept much higher than that of enzyme in order to prevent substrate concen-

tration dependency of the reaction rate at low substrate concentrations. The rate of an enzyme-catalyzed reaction will also show linearity to the enzyme concentration when substrate concentration is constant. The reaction rate will not reveal the linearity until the substrate is depleted, and the measurement in initial rate will be invalid. Preliminary experiments must be performed to determine the appropriate range of substrate concentrations over a number of enzyme concentrations to prevent the phenomenon of substrate depletion. In addition, the presence of inhibitor, activator, and cofactor in the reaction mixture also influence enzyme activity. The enzymatic activity will be low or undetectable in the presence of inhibitors or in the absence of activators or cofactors. In the case of cofactors, the activated enzymes will be proportional to the cofactor concentration added in the reaction mixture if enzymes are in excess. The rate of reaction will not represent the total amount of enzyme when the cofactor supplement is not sufficient, and the situation can be avoided by adding excess cofactors (Tipton 1992). Besides, loss of enzyme activity may be seen before substrate depletion, as when the enzyme concentration is too low and leads to the dissociation of the dimeric or multimeric enzyme. To test this possibility, addition of the same amount of enzyme can be applied to the reaction mixture to measure if there is the appearance of another reaction progression curve.

Effects of pH

Enzymes will exhibit maximal activity within a narrow range of pH and vary over a relatively broad range. For an assay of enzymatic catalysis, the pH of the solution of the reaction mixture must be maintained in an optimal condition to avoid pH-induced protein conformational changes, which lead to diminishment or loss of enzyme activity. A buffered solution, in which the pH is adjusted with a component with pK_a at or near the desired pH of the reaction mixture, is a stable environment that provides the enzyme with maximal catalytic efficiency. Thus, the appropriate pH range of an enzyme must be determined in advance when optimizing assay conditions.

To determine if the enzymatic reaction is pH dependent and to study the effects of group ionizations on enzyme kinetics, the rate as a function of substrate concentration at different pH conditions can be measured to simultaneously obtain the effects of pH on the kinetic parameters. It is known that the ionizations of groups are of importance, either for the active sites of the enzyme involved in the catalysis or for maintaining the active conformation of the enzyme. Plots of k_{cat}, K_m, and k_{cat}/K_m values at varying pH ranges will reflect important information about the roles of groups of the enzyme. The effect of pH dependence on the value of k_{cat} reveals the steps of ionization of groups involved in the ES complex and provides a pK_a value for the ES complex state; the value of K_m shows the ionizing groups that are essential to the substrate-binding step before the reaction. Moreover, the k_{cat}/K_m value reveals the ionizing groups that are essential to both the substrate-binding and the ES complex–forming steps, and provides the pK_a value of the free reactant molecules state (Brocklehurst and Dixon 1977, Copeland 2000). From a plot of the k_{cat}/K_m value on the logarithmic scale as a function of pH,
Figure 8.8. The effect of pH on the k_{cat}/K_m value of an enzymatic reaction that is not associated with the Henderson-Hasselbalch equation.

Figure 8.9. Plots of temperature effect on the energy levels of reactant molecules involved in a reaction. **(A)** The first plot depicts the distribution of energy levels of the reactant molecules at room temperature without the presence of an enzyme. **(B)** The second plot depicts that at the temperature higher than room temperature but in the absence of an enzyme. **(C)** The third plot depicts that at room temperature in the presence of an enzyme. The vertical line in each plot indicates the required activation energy level for a reaction to occur. The shaded portion of distribution in each plot indicates the proportion of reactant molecules that have enough energy levels to be involved in the reaction. The x-axis represents the energy level of reactant molecules, while the y-axis represents the frequency of reactant molecules at an energy level.

the pK_a value can be determined from the point of intersection of lines on the plot, especially for an enzymatic reaction that is not associated with the Henderson-Hasselbalch equation pH = $pK_a + \log([A^-]/[HA])$ (Fig. 8.8). Thus, the number of ionizing groups involved in the reaction can be evaluated (Dixon and Webb 1979, Tipton and Webb 1979).

EFFECTS OF TEMPERATURE

Temperature is one of the important factors affecting enzyme activity. For a reaction to occur at room temperature without the presence of an enzyme, small proportions of reactant molecules must have sufficient energy levels to participate in the reaction (Fig. 8.9A). When the temperature is raised above room temperature, more reactant molecules gain enough energy to be involved in the reaction (Fig. 8.9B). The E_A is not changed, but the distribution of energy-sufficient reactants is shifted to a higher average energy level. When an enzyme is participating in the reaction, the E_A is lowered significantly, and the proportion of reactant molecules at an energy level above the activation energy is also greatly increased (Fig. 8.9C). That means the reaction will proceed at a much higher rate.

Most enzyme-catalyzed reactions are characterized by an increase in the rate of reaction and increased thermal instability of the enzyme with increasing temperature. Above the critical temperature, the activity of the enzyme will be reduced significantly; while within this critical temperature range, the enzyme activity will remain at a relatively high level, and inactivation of the enzyme will not occur. Since the rate of reaction increases due to the increased temperature by lowering the activation energy E_A, the relationship can be expressed by the Arrhenius equation: $k = A \exp(-E_A/RT)$, where A is a constant related to collision probability of reactant molecules, R is the ideal gas constant (1.987 cal/mol—deg), T is the temperature in degrees Kelvin (K = °C + 273.15), and k represents the specific rate constant for any rate, that is, k_{cat} or V_{max}. The equation can be transformed into: $\ln K = \ln A - E_A/RT$, where the plot of $\ln K$ against $1/T$ usually shows a linear relationship with a slope of $-E_A/R$, where the unit of E_A is cal/mol. The calculated E_A of a reaction at a particular temperature is useful in predicting the E_A of the reaction at another temperature. And the plot is

useful in judging if there is a change in the rate-limiting step of a sequential reaction when the line of the plot reveals bending of different slopes at certain temperatures (Stauffer 1989).

Taken together, the reaction should be performed under a constantly stable circumstance, with both temperature and pH precisely controlled from the start to the finish of the assay, for the enzyme to exhibit highly specific activity at appropriate acidbase conditions and buffer constitutions. Whenever possible, the reactant molecules should be equilibrated at the required assay condition following addition of the required components and efficient mixing to provide a homogenous reaction mixture. Because the enzyme to be added is usually stored at low temperature, the reaction temperature will not be significantly influenced when the enzyme volume added is at as low as 1–5% of the total volume of the reaction mixture. A lag phase will be noticed in the rate measurement as a function of time when the temperature of the added enzyme stock eventually influences the reaction. Significant temperature changes in the components stored in different environments and atmospheres should be avoided when the reaction mixture is mixed and the assay has started.

METHODS USED IN ENZYME ASSAYS

GENERAL CONSIDERATIONS

A suitable assay method is not only a prerequisite for detecting the presence of enzyme activity in the extract or the purified material: it is also an essential vehicle for kinetic study and inhibitor evaluation. Selection of an assay method that is appropriate to the type of investigation and the purity of the assaying material is of particular importance. It is known that the concentration of the substrate will decrease and that of product will increase when the enzyme is incubated with its substrate. Therefore, an enzyme assay is intended to measure either the decrease in substrate concentration or the increase in product concentration as a function of time. Usually, the latter is preferred because a significant increase of signal is much easier to monitor. It is recommended that a preliminary test be performed to determine the optimal conditions for a reaction including substrate concentration, reaction temperature, cofactor requirements, and buffer constitutions, such as pH and ionic strength, to ensure the consistency of the reaction. Also, an enzyme blank should be performed to determine if the nonenzymatic reaction is negligible or could be corrected. When a crude extract, rather than purified enzyme, is used for determining enzyme activity, one control experiment should be performed without adding substrate to determine if there are any endogenous substrates present and to prevent overcounting of the enzyme activity in the extract.

Usually, the initial reaction rate is measured, and it is related to the substrate concentration. Highly sufficient substrate concentration is required to prevent a decrease in concentration during the assay period of enzyme activity, thus allowing the concentration of the substrate to be regarded as constant.

TYPES OF ASSAY METHODS

On the basis of measuring the decrease of the substrate or the increase of the product, one common characteristic property that is useful for distinguishing the substrate and the product is their absorbance spectra, which can be determined using one of the *spectrophotometric methods*. Observation of the change in absorbance in the visible or near UV spectrum is the method most commonly used in assaying enzyme activity. $NAD(P)^+$ is quite often a cofactor of dehydrogenases, and NAD(P)H is the resulting product. The absorbance spectrum is 340 nm for the product, NAD(P)H, but not for the cofactor, NAD $(P)^+$. A continuous measurement at absorbance 340 nm is required to continuously monitor the disappearance of the substrate or the appearance of the product. This is called a *continuous assay*, and it is also a *direct assay* because the catalyzed reaction itself produces a measurable signal. The advantage of continuous assays is that the progress curve is immediately available, as is confirmation that the initial rate is linear for the measuring period. They are generally preferred because they give more information during the measurement. However, methods based on fluorescence, the *spectrofluorometric methods*, are more sensitive than those based on the changes in the absorbance spectrum. The reaction is accomplished by the release or uptake of protons and is the basis of performing the assay. Detailed discussions on the assaying techniques are available below.

Sometimes, when a serial enzymatic reaction of a metabolic pathway is being assayed, no significant products, the substrates of the next reaction, can be measured in the absorbance spectra due to rapid changes in the reaction. Therefore, there may be no suitable detection machinery available for this single enzymatic study. Nevertheless, there is still a measurable signal when one or several enzymatic reactions are coupled to the desired assay reaction. These are *coupled assays*, one of the particular *indirect assays* whose coupled reaction is not enzymatic. This means that the coupled enzymes and the substrates have to be present in excess to make sure that the rate-limiting step is always the reaction of the particular enzyme being assayed. Though a lag in the appearance of the preferred product will be noticed at the beginning of the assay, before reaching a steady state, the phenomenon will only appear for a short period of time if the concentration of the coupling enzymes and substrates are kept in excess. So, the V_{max} of the coupling reactions will be greater than that of the preferred reaction. Besides, not only the substrate concentration but also other parameters may affect the preferred reaction (see previously). To prevent this, control experiments can be performed to check if the V_{max} of the coupling reactions is actually much higher than that of the preferred reaction. For other indirect assays in which the desired catalyzed reaction itself does not produce a measurable signal, a suitable reagent that has no effect on enzyme activity can be added to the reaction mixture to react with one of the products to form a measurable signal.

Nevertheless, sometimes no easily readable differences between the spectrum of absorbance of the substrate and that of the product can be measured. In such cases, it may be possible to measure the appearance of the colored product, by the

chromogenic method (one of the spectrofluorometric methods). The reaction is incubated for a fixed period of time. Then, because the development of color requires the inhibition of enzyme activity, the reaction is stopped and the concentration of colored product of the substrate is measured. This is the *discontinuous* or *end point assay*. Assays involving product separation that cannot be designed to continuously measure the signal change, such as electrophoresis, high performance liquid chromatography (HPLC), and sample quenching at time intervals, are also discontinuous assays. The advantage of discontinuous assays is that they are less time consuming for monitoring a large number of samples for enzyme activity. However, additional control experiments are needed to ensure that the initiation rate is linear for the measuring period of time. Otherwise, the radiolabeled substrate of an enzyme assay is a highly sensitive method that allows the detection of radioactive product. Separation of the substrate and the product by a variety of extraction methods may be required to accurately assay the enzyme activity.

DETECTION METHODS

Spectrophotometric Methods

Both the spectrophotometric method and the spectrofluorometric method discussed below use measurements at specific wavelengths of light energy (in the wavelength regions of 200–400 nm (UV, ultraviolet) and 400–800 nm (visible)) to determine how much light has been absorbed by a target molecule (resulting in changes in electronic configuration). The measured value from the spectrophotometric method at a specific wavelength can be related to the molecule concentration in the solution using a cell with a fixed path length (l cm) that obeys the Beer-Lambert law:

$$A = -\log T = \varepsilon c l,$$

where A is the absorbance at certain wavelength, T is the transmittance, representing the intensity of transmitted light, ε is the extinction coefficient, and c is the molar concentration of the sample. Using this law, the measured change in absorbance, ΔA, can be converted to the change in molecule concentration, Δc, and the change in rate, v_i, can be calculated as a function of time, Δt, that is, $v_i = \Delta A / \varepsilon l \Delta t$.

Choices of appropriate materials for spectroscopic cells (cuvettes) depend on the wavelength used; quartz cuvettes must be used at wavelengths less than 350 nm because glass and disposable plastic cuvettes absorb too much light in the UV light range. However, the latter glass and disposable plastic cuvettes can be used in the wavelength range of 350–800 nm. Selection of a wavelength for the measurement depends on finding the wavelength that produces the greatest difference in absorbance between the reactant and product molecules in the reaction. Though the wavelength of measurement usually refers to the maximal wavelength of the reactant or product molecule, the most meaningful analytical wavelength may not be the same as the maximum wavelength because significant overlap of spectra may be found between the reactant and product molecules. Thus, a different spectrum between two molecules can be calcu-

lated to determine the most sensitive analytical wavelengths for monitoring the increase in product and the decrease in substrate.

Spectrofluorometric Methods

When a molecule absorbs light at an appropriate wavelength, an electronic transition occurs from the ground state to the excited state; this short-lived transition decays through various high-energy, vibrational substrates at the excited electronic state by heat dissipation, and then relaxes to the ground state with a photon emission, the fluorescence. The emitted fluorescence is less energetic (longer wavelength) than the initial energy that is required to excite the molecules; this is referred to as the Stokes shift. Taking advantage of this, the fluorescence instrument is designed to excite the sample and detect the emitted light at different wavelengths. The ratio of quanta fluoresced over quanta absorbed offers a value of quantum yield (Q), which measures the efficiency of the reaction leading to light emission. The light emission signals vary with concentration of fluorescent material by the Beer-Lambert law, where the extinction coefficient is replaced by the quantum yield, and gives: $I_f = 2.31 \ I_0 \varepsilon c l Q$, where I_f and I_0 are the intensities of light emission and of incident light that excites the sample, respectively. However, conversion of light emission values into concentration units requires the preparation of a standard curve of light emission signals as a function of the fluorescent material concentration, which has to be determined independently, due to the not strictly linear relationship between I_f and c (Lakowicz 1983).

Spectroflurometric methods provide highly sensitive capacities for detection of low concentration changes in a reaction. However, quenching (diminishing) or resonance energy transfer (RET) of the measured intensity of the donor molecule will be observed if the acceptor molecule absorbs light and the donor molecule emits light at the same wavelength. The acceptor molecule will either decay to its ground state if quenching occurs or fluoresce at a characteristic wavelength if energy is transferred (Lakowicz 1983). Both situations can be overcome by using an appropriate peptide sequence, up to 10 or more amino acid residues, to separate the fluorescence donor molecule from the acceptor molecule if peptide substrates are used. Thus, both effects can be relieved by cleaving the intermolecular bonding when protease activity is being assayed.

Care should be taken in performing the spectrofluorometric method. For instance, the construction of a calibration curve as the experiment is assayed is essential, and the storage conditions for the fluorescent molecules are important because of photodecomposition. In addition, the quantum yield is related to the temperature, and the fluorescence signal will increase with decreasing temperature, so a temperature-constant condition is required (Bashford and Harris 1987, Gul et al. 1998).

Radiometric Methods

The principle of the radiometric methods in enzymatic catalysis studies is the quantification of radioisotopes incorporated into the substrate and retained in the product. Hence, successful radiometric methods rely on the efficient separation of the

radiolabled product from the residual radiolabeled substrate and on the sensitivity and specificity of the radioactivity detection method. Most commonly used radioisotopes, for example, ^{14}C, ^{32}P, ^{35}S, and ^{3}H, decay through emission of β particles; however, ^{125}I decays through emission of γ particles, whose loss is related to loss of radioactivity and the rate of decay (the half-life) of the isotope. Radioactivity expressed in Curies (Ci) decays at a rate of 2.22×10^{12} disintegrations per minute (dpm); expressed in Becquerels (Bq), it decays at a rate of 1 disintegrations per second (dps). The experimental units of radioactivity are counts per minute (cpm) measured by the instrument; quantification of the specific activity of the sample is given in units of radioactivity per mass or per molarity of the sample (e.g., μCi/mg or dpm/μmol).

Methods of separation of radiolabeled product and residual radiolabeled substrate include chromatography, electrophoresis, centrifugation, and solvent extraction (Gul et al. 1998). For the detection of radioactivity, one commonly used instrument is a scintillation counter that measures light emitted when solutions of p-terphenyl or stilbene in xylene or toluene are mixed with radioactive material designed around a photomultiplier tube. Another method is the autoradiography that allows detecting radioactivity on surfaces in close contact either with X-ray film or with plates of computerized phosphor imaging devices. Whenever operating the isotopescontaining experiments, care should always be taken for assuring safety.

Chromatographic Methods

Chromatography is applied in the separation of the reactant molecules and products in enzymatic reactions and is usually used in conjunction with other detection methods. The most commonly used chromatographic methods include paper chromatography, column chromatography, thin-layer chromatography (TLC), and HPLC. Paper chromatography is a simple and economic method for the readily separation of large numbers of samples. By contrast, column chromatography is more expensive and has poor reproducibility. The TLC method has the advantage of faster separation of mixed samples, and like paper chromatography, it is disposable and can be quantified and scanned; it is not easily replaced by HPLC, especially for measuring small, radiolabeled molecules (Oldham 1992).

The HPLC method featured with low compressibility resins is a versatile method for the separation of either low molecular weight molecules or small peptides. Under a range of high pressures up to 5000 psi (which approximates to 3.45×10^{7} Pa), the resolution is greatly enhanced with a faster flow rate and a shorter run time. The solvent used for elution, referred to as the mobile phase, should be an HPLC grade that contains low contaminants; the insoluble media is usually referred to as the stationary phase. Two types of mobile phase are used during elution; one is an isocratic elution whose composition is not changed, and the other is a gradient elution whose concentration is gradually increased for better resolution. The three HPLC methods most commonly used in the separation steps of enzymatic assays are reverse phase, ion-exchange, and size-exclusion chromatography.

The basis of reverse phase HPLC is the use of a nonpolar stationary phase composed of silica covalently bonded to alkyl silane, and a polar mobile phase used to maximize hydrophobic interactions with the stationary phase. Molecules are eluted in a solvent of low polarity (e.g., methanol, acetonitrile, or acetone mixed with water at different ratios) that is able to efficiently compete with molecules for the hydrophobic stationary phase.

The ion-exchange HPLC contains a stationary phase covalently bonded to a charged functional group; it binds the molecules through electrostatic interactions, which can be disrupted by the increasing ionic strength of the mobile phase. By modifying the composition of the mobile phase, differential elution, separating multiple molecules, is achieved.

In the size-exclusion HPLC, also known as gel filtration, the stationary phase is composed of porous beads with a particular molecular weight range of fractionation. However, this method is not recommended where molecular weight differences between substrates and products are minor, because of overlapping of the elution profiles (Oliver 1989).

Selection of the HPLC detector depends on the types of signals measured, and most commonly the UV/visible light detectors are extensively used.

Electrophoretic Methods

Agarose gel electrophoresis and polyacrylamide gel electrophoresis (PAGE) are widely used methods for separation of macromolecules; they depend, respectively, on the percentage of agarose and acrylamide in the gel matrix. The most commonly used method is the sodium dodecyl sulfate (SDS)-PAGE method; under denaturing conditions, the anionic detergent SDS is coated on peptides or proteins giving them equivalently the same anionic charge densities. Resolving of the samples will thus be based on molecular weight under an electric field over a period of time. After electrophoresis, peptides or proteins bands can be visualized by staining the gel with Coomassie Brilliant Blue or other staining reagents, and radiolabeled materials can be detected by autoradiography. Applications of electrophoresis assays are not only for detection of molecular weight and radioactivity differences, but also for detection of charge differences. For instance, the enzyme-catalyzed phosphorylation reactions result in phosphoryl transfer from substrates to products, and net charge differences between two molecules form the basis for separation by electrophoresis. If radioisotope ^{32}P-labeled phosphate is incorporated into the molecules, the reactions can be detected by autoradiography, by monitoring the radiolabel transfer after gel electrophoresis, or by immunological blotting with antibodies that specifically recognize peptides or proteins containing phosphate-modified amino acid residues.

Native gel electrophoresis is also useful in the above applications, where not only the molecular weight but also the charge density and overall molecule shape affect the migration of molecules in gels. Though SDS-PAGE causes denaturing to peptides and proteins, renaturation in gels is possible and can be applied to several types of in situ enzymatic activity studies such as activity staining and zymography (Hames and Rickwood

1990). Both methods assay enzyme activity after electrophoresis, but zymography is especially intended for proteolytic enzyme activity staining in which gels are cast with high concentrations of proteolytic enzyme substrates, for example, casein, gelatin, bovine serum albumin, collagen, and others. Samples containing proteolytic enzymes can be subjected to gel electrophoresis, but the renaturation step has to be performed if a denaturing condition is used; then the reaction is performed under conditions suitable for assaying proteolytic enzymes. The gel is then subjected to staining and destaining, but the entire gel background will not be destained because the gel is polymerized with protein substrates, except in clear zones where the significant proteolysis has occurred; the amount of staining observed will be greatly diminished due to the loss of protein. This process is also known as reverse staining. Otherwise, reverse zymography is a method used to assay the proteolytic enzyme inhibitor activity in gel. Similar to zymography, samples containing proteolytic enzyme inhibitor can be subjected to gel electrophoresis. After the gel renaturation step is performed, the reaction is assayed under appropriate conditions in the presence of a specific type of proteolytic enzyme. Only a specific type of proteolytic enzyme inhibitor will be resistant to the proteolysis, and after staining, the active proteolytic enzyme inhibitor will appear as protein band (Oliver et al. 1999).

Other Methods

The most commonly used assay methods are the spectrophotometric, spectrofluorometric, radiometric, chromatographic, and electrophoretic methods described above, but a variety of other methods are utilized as well. Immunological methods make use of the antibodies raised against the proteins (Harlow and Lane 1988). Polarographic methods make use of the change in current related to the change in concentration of an electroactive compound that undergoes oxidation or reduction (Vassos and Ewing 1983). Oxygen-sensing methods make use of the change in oxygen concentration monitored by an oxygen-specific electrode (Clark 1992), and pH-stat methods use measurements of the quantity of base or acid required to be added to maintain a constant pH (Jacobsen et al. 1957).

SELECTION OF AN APPROPRIATE SUBSTRATE

Generally, a low molecular mass, chromogenic substrate containing one susceptible bond is preferred for use in enzymatic reactions. A substrate containing many susceptible bonds or different functional groups adjacent to the susceptible bond may affect the cleavage efficiency of the enzyme, and this can result in the appearance of several intermediate-sized products. Thus, they may interfere with the result and make interpretation of kinetic data difficult. Otherwise, the chromophore-containing substrate will readily and easily support assaying methods with absorbance measurement. Moreover, substrate specificity can also be precisely determined when an enzyme has more than one recognition site on both the preferred bond and the functional groups adjacent to it. Different sized chromogenic substrates can then be used to determine an enzyme's specificity and to quantify its substrate preference.

UNIT OF ENZYME ACTIVITY

The unit of enzyme activity is usually expressed as either micromoles of substrate converted or product formed per unit time, or unit of activity per milliliter under a standardized set of conditions. Though any unit of enzyme activity can be used, the Commission on Enzymes of the International Union of Biochemistry and Molecular Biology (IUBMB) has recommended that a unit of enzyme, Enzyme Unit or International Unit (U), be used. An Enzyme Unit is defined as that amount that will catalyze the conversion of 1 micromole of substrate per minute, $1 \text{ U} = 1 \ \mu\text{mol/min}$, under defined conditions. The conditions include substrate concentration, pH, temperature, buffer composition, and other parameters that may affect the sensitivity and specificity of the reaction, and usually a continuous spectropotometric method or a pH stat method is preferred. Another enzyme unit that now is not widely used is the International System of Units (SI unit) in which 1 katal (kat) = 1 mol/sec, so 1 kat = 60 mol/min = 6×10^7 U.

In ascertaining successful purification of a specified enzyme from an extract, it is necessary to compare the specific activity of each step to that of the original extract; a ratio of the two gives the fold purification. The specific activity of an enzyme is usually expressed as units per milligram of protein when the unit of enzyme per milliliter is divided by milligrams of protein per milliliter, the protein concentration. The fold purification is an index reflecting only the increase in the specific activity with respect to the extract, not the purity of the specified enzyme.

Enzymes in Food Processing

Benjamin K. Simpson, Xin Rui, and Sappasith Klomklao

Abstract: Enzymes have been used as food processing aids since time immemorial. Enzyme action in foods manifests as sensory, textural, and color changes that may or may not be desirable in the products, depending on the nature of the transformation. Their use as food processing aids is desirable, perhaps preferable to other food processing methods, because they are perceived as natural components of food; they are also more specific and can be used in low concentrations under mild reaction conditions. The products formulated with enzymes tend to be more uniform, and their action in

foods can be stopped relatively easily after the desired transformation is attained. The chapter is organized in six sections and covers the major groups and sources of food enzymes, their properties and modes of action, the rationale for their use in food, their use in the manufacture of various foods, and the different strategies employed to control their undesirable effects in foods. The chapter also provides information on the future prospects of enzymes.

INTRODUCTION

Enzymes are biological molecules that enable biological reactions proceed at perceptible rates in living organisms (plants, animals, and microorganisms) and the products derived from these sources. Living organisms produce basically the same functional classes of enzymes to enable them carry out similar metabolic processes in their cells and tissues. Thus, it is to be expected that foodstuffs would also possess endogenous enzymes to catalyze biological reactions that occur in them both pre- and postharvest. The molecules that enzymes act upon are called substrates, while the resulting compounds from the enzymatic conversions are called products. Enzymes are able to speed up biological reactions by lowering the free energy of activation (ΔG^*) of the reaction (van Oort 2010). Unlike chemical catalysts, enzymes are much more specific and active under mild reaction conditions of pH, temperature, and ionic strength.

Humans have intentionally or unintentionally used enzymes to modify foodstuffs to alter their functional properties, extend their storage life, improve flavors, and provide variety and delight, and the use of enzymes in food processing has been increasing for reasons such as consumer preferences for their use in food modification instead of chemical treatments, their capacity to retain high nutritive value of foods, and the advances in biotechnology that are enabling the discoveries of new enzymes that are much more efficient in transforming foods. The recent advances in molecular biotechnology that are permitting the discoveries of new and better food enzymes augur well both for the need and capacity for food technologists and food manufacturers to produce food products in highly nutritious, safe, and stable forms as part of the overall strategy to achieve food security.

However, not all reactions catalyzed by enzymes in foods are useful; naturally present enzymes in fresh foods and their counterparts that survive food-processing operations can induce undesirable changes in foods, some of which may even be toxic. Thus, there is the need to also develop novel and more effective strategies to control the deleterious effects of enzymes in foods to reduce postharvest food losses and/or spoilage.

Some Terms and Definitions

Several useful terms are encountered in the study of enzymes. The active enzyme molecule may comprise a protein part exclusively, or the enzyme protein may require as essential nonprotein part for its functional activity. The essential nonprotein part that some enzymes require for functional activity is known as a cofactor or prosthetic group. For those enzymes requiring cofactors for activity, the enzyme–cofactor complex is known as the holoenzyme, and the protein part that has no functional activity without the cofactor is known as apoenzyme. Thus, cofactors or prosthetic groups may be regarded as "helper molecules" for the apoenzymes. Cofactors may be inorganic (e.g., metal ions like Zn, Mg, Mn, and Cu), or organic (e.g., riboflavin, thiamine, or folic acid) materials. Examples of food enzymes that do not require cofactors or prosthetic groups for activity include lysozyme, pepsin, trypsin, and chymotrypsin; examples of those enzymes that require cofactors or prosthetic groups for functional activity include carboxypeptidase, carbonic anhydrase and alcohol dehydrogenase (all have Zn^{2+} as cofactor), cytochrome oxidase (has Cu^{2+} as cofactor), glutathione peroxidase (which has Se cofactor), catalase (with either Fe^{2+} or Fe^{3+} as cofactor), and pyruvate carboxylase (that has thiamine in the form of thiamin pyrophosphate or TPP as cofactor).

Enzymes have a catalytic region known as the active site where substrate molecules (S) bind prior to their transformation into products (P). The active site is a very small region of the very large enzyme molecule, and the transformation of substrates to products may be measured by either the rate of disappearance of the substrate ($-\delta S/\delta t$) or the rate of appearance of the products ($\delta P/\delta t$) in the reaction mixture. The activity of the enzyme is usually expressed in units, where a unit of activity may be defined as the amount of enzyme required to convert 1 μmol of the substrate per unit time under specified conditions (e.g., temperature, pH, ionic strength, and/or substrate concentration). Enzyme activity may also be expressed in terms of specific activity, which may be defined as the number of enzyme units per unit amount (e.g., milligram) of enzyme; or it may be denoted by the molecular activity or turnover number, defined as the number of enzyme units per mol of the enzyme at optimal substrate concentration. The efficiency of an enzyme (catalytic efficiency) may be derived from knowledge of the binding capacity of the enzyme for the substrate (K'_m, which is the apparent Michaelis–Menten constant) and the subsequent transformation of the substrate into products (K_{cat} or V_{max}). The catalytic efficiency of an enzyme is defined as the ratio of the maximum velocity (V_{max}) of the transformation of the substrate(s) into product(s) to the binding capacity of the enzyme (or the apparent Michaelis–Menten constant, K'_m, i.e., V_{max}/K'_m or K_{cat}/K'_m). The catalytic efficiency is a useful parameter in selecting more efficient enzymes from a group of homologous enzymes for carrying out particular operations.

Rationale for Interest in Food Enzymes

Beneficial Effects

Enzymes have several advantages for food use compared to conventional chemical catalysts. They are relatively more selective and specific in their choice and action on substrates, thus obviating side reactions that could lead to the formation of undesirable coproducts in the finished products. They have higher efficiency and can conduct reactions several times faster than other catalysts. They are active in low concentrations and perform well under relatively mild reaction conditions (e.g., temperature and pH); thus, their use in food processing helps to preserve the integrity of heat-labile essential nutrients. They can also be

immobilized onto stationary support materials to permit their reuse and thereby reduce processing costs. Most of them are quite heat labile; thus, they can be readily inactivated by mild heat treatments after they have been used to achieve the desired transformation in foods, and they are natural and relatively innocuous components of agricultural materials that are considered "safe" for food and other nonfood uses (e.g., drugs and cosmetics). Their action on food components other than their substrates are negligible, and more gentle, thus resulting in the formation of purer products with more consistent properties; and they are also more environmentally friendly and produce less residuals (or processing waste that must be disposed of at high costs) compared to traditional chemical catalysts (van Oort 2010). Because of these beneficial effects, enzymes are used in the food industry for a plethora of applications including: baking and milling, production of (both alcoholic and nonalcoholic beverages), cheese and other dairy products manufacture, as well as the manufacture of eggs and egg products, fish and fish products, meats and meat products, cereal and cereal products, and in confectionaries.

Undesirable Effects

Certain food enzymes cause undesirable autolytic changes in food products, such as excessive proteolysis to produce bitterness in cheeses and protein hydrolysates, or excessive texture softening in meats and fish products (e.g., canned tuna). Enzymes like proteases, lipases, and carbohydrases break down biological molecules (proteins, fats, and carbohydrates, respectively) to adversely impact flavor, texture, and keeping qualities of the products. Decarboxylases and deaminases degrade biomolecules (e.g., free amino acids, peptides, and proteins) to form undesirable and/or toxic components, e.g., biogenic amines, in foods. Some others, for example, polyphenol oxidases (PPO) and lipoxygenases (LOX), promote oxidations and undesirable discolorations and/or color loss in fresh vegetables, fruits, crustacea, and salmonids, and others like thiaminase and ascorbic acid oxidase cause destruction of essential components (vitamins) in foods. Thus, more effective treatments must be developed and implemented to safeguard against such undesirable effects of enzymes in foods.

SOURCES OF FOOD ENZYMES (PLANT, ANIMAL, MICROBIAL, AND RECOMBINANT)

Enzymes have been used inadvertently or deliberately in food processing since ancient times to make a variety of food products, such as breads, fermented alcoholic beverages, fish sauces, and cheeses, and for the production of several food ingredients. Enzymes have been traditionally produced by extraction and fermentation processes from plant and animal sources, as well as from a few cultivatable microorganisms.

Industrial enzymes have traditionally been derived from plant, animal, and microbial sources (Table 9.1). Examples of plant enzymes include α-amylase, β-amylase, bromelain, β-glucanase, ficin, papain, chymopapain, and LOX; examples of animal enzymes are trypsins, pepsins, chymotrypsins, catalase, pancreatic amylase, pancreatic lipase, and rennet; and examples of microbial enzymes are α-amylase, β-amylase, glucose isomerase, pullulanase, cellulase, catalase, lactase, pectinases, pectin lyase, invertase, raffinose, microbial lipases, and proteases.

Microorganisms constitute the foremost enzyme source because they are easier and faster to grow and take lesser space to cultivate, and their use as enzyme source is not affected by seasonal changes and inclement climatic conditions and are thus more consistent. Their use as sources of enzymes is also not affected by various political and agricultural policies or decisions that regulate the slaughter of animals or felling of trees or plants. Industrial microbial enzymes are obtained from bacteria (e.g., α- and β-amylases, glucose isomerase, pullulanase, and asparaginase), yeasts (e.g., invertase, lactase, and raffinose), and fungi (e.g., glucose oxidase (GOX), catalase, cellulase, dextranase, glucoamylase, pectinases, pectin lyase, and fungal rennet). Even though all classes of enzymes are expected to occur in all or most microorganisms, in practice, the great majority of industrial microbial enzymes are derived from only a very few GRAS (generally recognized as safe) species, the predominant ones being types like *Aspergillus* species, *Bacillus* species, and *Kluyveromyces* species. This is because microorganisms can coproduce harmful toxins, and therefore need to be stringently evaluated for safety at high cost before they can be put to use for food production. As such, there are only very few microorganisms currently used as safe sources of enzymes and most of these strains have either been used by the food industry for several years or been derived from such strains by genetic mutation and selection.

The traditionally produced enzymes are invariably not well suited for efficient use in food-processing applications for reasons such as sensitivity to processing temperature and pH, inhibitory reaction components naturally present in foods, as well as availability, consistency, and cost. Recent developments in industrial biotechnology (including recombinant DNA and fermentation technologies) have permitted molecular biologists and food manufacturers to design and manufacture novel enzymes tailor-made to suit particular food-processing applications (Olempska-Beer et al. 2006). These new microbial enzymes are adapted to have specific characteristics that make them better suited to function under extreme environmental conditions, e.g., pH and temperature. The production of recombinant enzymes by recombinant DNA technology entails the introduction of the genes that encode for those enzymes from traditional sources into special vectors to produce large amounts of the particular enzyme. Recombinant enzymes are useful because they can be produced to a high degree of purity, and they can be produced in high yields and made available on a continuing and consistent basis at much reduced cost. As well, their purity and large-scale production reduce extensive quality assurance practices; and the technique itself enables useful (food) enzymes from unsafe organisms to be produced in useful forms as recombinant enzymes in safer microorganisms.

Examples of recombinant enzymes available for food use include various amylases, lipases, chymosins, and GOX.

Table 9.1. Sources of Industrial Food Enzymes—Selected Traditional and Recombinant Forms

Source	Enzyme	Some Food Applications
Plant sources		
Papaya tree	Papain	Meats, baked goods, brewing
Pineapple stem	Bromelain	Meats, baked goods
Animal sources		
Stomachs of ruminants	Chymosin (rennet)	Dairy (cheese)
Mammals (guts)	Lipase	Dairy products, oleo products, baked goods
Microbial sources		
Bacillus spp.	Alcalase	Waste utilization, bioactive compounds
	α-Amylase	Baked goods, beverages, and high-glucose syrups
	β-Amylase	Baked goods, beverages, and high-glucose syrups
	Pectinase (alkaline)	Fruit juices, coffee, and tea
	α-D-Galactosidase	Soybean pretreatment
Aspergillus niger	Protease	Soy sauce
	Pectinase (acidic)	Fruit juices
	Lipase	Dairy products, oleo products, baked goods
	Glucose oxidase	Baked goods, beverages, dried food mixes
Aspergillus niger, Candida guilliermondii, Kluyveromyces marxianus	Fructosidase	Fructose production
Candida cylindracea, Penicillium spp., Rhizopus spp., Mucor spp.	Lipase	Dairy products, oleo products, baked goods
Aspergillus spp., Penicillium spp., Aureobasidium spp.	Fructosyl transferase	Fructo-oligosaccharides production
Streptoverticillium mobaraense	Transglutaminase (TGase)	Meats, seafood, dairy products
Pleurotus ostreatus	Laccase	Beverages (wine, fruit juice, beer), jams, baked goods
Recombinant enzymes[a]		
Aspergillus oryzae	Aspartic proteinase	Meats (potential as tenderizer)
	Chymosin	Dairy (cheese)
	Glucose oxidase	Baked goods, beverages, dried food mixes
	Laccase	Beverages (wine, fruit juice, beer), jams, baked goods
	Lipase	Dairy products, oleo products, baked goods
	Pectin esterase	Beverages (wine, fruit juice, beer)
	Phytase	Baked goods, animal feeds
Aspergillus oryzae, Pichia pastoris	Phospholipase A$_1$	Refining of vegetable oils
Bacillus lichenformis	α-Amylase	Baked goods, beverages, and high-glucose syrups
	Pullulanase	Baked goods, beverages, and high-glucose syrups
Bacillus subtilis	α-Acetolactate dehydrogenase	Dairy, flavor generation
Escherichia coli K-12	Chymosin	Dairy (cheese)
Fusarium venenatum	Xylanase	Cereals, baked goods, animal feed
Kluyveromyces maxianus var. *lactis*	Chymosin	Dairy (cheese)
Pseudomonas fluorenscens Biovar 1	α-Amylase	Baked goods, beverages, and high-glucose syrups
Trichoderma reesei	Pectin lyase	Beverages (wine, fruit juice, beer)

[a]Olempska-Beer et al. (2006).

Table 9.1 also lists other recombinant food enzymes, their source microorganisms, and their food applications, as well as those of their traditional counterparts.

MAJOR FOOD ENZYMES BY GROUPS

The major enzymes used in the food industry include various members from the oxidoreductase, transferase, hydrolase, and isomerase families of enzymes. The oxidoreductases catalyze oxidation–reduction reactions in their substrates. Examples of the oxidoreductases are catalases, GOXs, LOX, PPO, and peroxidases. The transferases catalyze the transfer of groups between molecules to results in new molecules or form inter-/intramolecular cross-linkages in their substrates. An example of transferase used in the food industry is transglutaminase (TGase). The hydrolases catalyze the hydrolytic splitting

of large molecules (e.g., proteins, carbohydrates, lipids, and nucleic acids) into smaller ones (e.g., amino acids and peptides; mono-, di-, and oligosaccharides; free fatty acids, mono-, and di-glycerides; nucleotides and purines). Examples of the hydrolases include the proteases, carbohydrases, lipases, and nucleases. The isomerases potentiate intramolecular rearrangements in their substrate molecules. An example of isomerase used in food processing is xylose isomerase (also known as glucose isomerase).

OXIDOREDUCTASES

Oxidoreductases are the group of enzymes that catalyze oxidation–reduction reactions in their substrates. They occur widely in plants, animals, and microorganisms. In the food industry, the oxidoreductases of economic importance include GOX, PPO, peroxidase and catalase, lipoxygenase, xanthine oxidase (XO), ascorbic acid oxidase, and sulfhydryl oxidase (SO). Other well-known oxidoreductases are alcohol dehydrogenase, aldehyde dehydrogenase, lactate dehydrogenase (LDH), glutathione dehydrogenase, laccases, and lactoperoxidase.

Glucose Oxidase

GOX is produced commercially from the fungi *Aspergillus niger*, *Penicillium chrysogenum* (formerly known as *P. notatum*), *P. Amagaskinese,* and *P. vitale*. GOX catalyzes the oxidation of β-D-glucose initially to D-glucono-δ-lactone and hydrogen peroxide (H_2O_2); the gluconolactone is subsequently hydrolyzed to D-gluconic acid. In the food industry, GOX is used to improve bread dough texture (in place of oxidants like ascorbate or bromate), and the H_2O_2 formed as coproduct in the oxidation of D-glucose facilitates formation of a network of disulfide bonds through the oxidation of thiol groups in proteins and cysteine to result in stronger doughs. GOX is used in the food industry to desugar egg white and prevent Maillard-type browning reactions, and is also used in combination with catalase to eliminate O_2 from the head spaces of beverages (e.g., wines) and dried food packages to curtail enzymatic browning reactions and off-flavor development.

Polyphenol Oxidase

The term PPO is used here to encompass all those enzymes that have variously been referred to as catecholase, cresolase, diphenolase, laccase, phenolase, polyphenolase, or tyrosinase. PPO is widespread in nature and occurs in plants, animals, and microorganisms, and is produced on a large scale from mushrooms and by fermentation from fungi such as *Alternaria tenius*, *Chaetomium thermophile,* and *Thermomyces lanuginosus*, and from bacteria, particularly from the genus *Bacillus* such as *B. licheniformis*, *B. Natto,* and *B. sphaericus*. They are Cu^{++}-containing enzymes and enhance enzymatic browning, whereby phenolic compounds are hydroxylated and/or oxidized via intermediates such as quinones that polymerize into dark-colored pigments known as melanins. These browning reactions are responsible for the undesirable darks discoloration in bruised or freshly cut fruits (e.g., apples, avocadoes, and bananas) and veg-

etables (e.g., lettuce and potatoes), as well as in melanosis or "blackspot" formation in raw crustacea (e.g., shrimps, lobsters, crabs). Nonetheless, PPO-induced browning is desirable in other products such as chocolate, cocoa, coffee, prunes, raisins, tea, and tobacco.

In the food industry, PPO is used to enhance the color and flavor in coffee, tea, and cocoa. PPO is also put to nonfood uses in the pharmaceutical and biomedical industries: as components of biosensors for distinguishing between codeine and morphine; for the treatment of Parkinson's disease, phenylketonuria, and leukemia; and in wastewater treatment for the removal of phenolic pollutants.

Lipoxygenase

LOX, also known as lipoxidases, are non-heme, iron-containing enzymes that are found in plants, animals, and microorganisms. LOX is obtained for commercial use from soy flour. The enzyme causes oxidization of essential unsaturated fatty acids, e.g., oleic, linoleic, linolenic, arachidonic, and other polyunsaturated fatty acids such as eicosapentaenoic acid and docosahexaenoic acid, as well as carotenoids, to form their breakdown products (e.g., hydrocarbons, alcohols, carbonyl compound, and epoxides). As a result of the activities of LOX, off flavors develop in foodstuffs (oxidative rancidity); as well, there is formation of free radical intermediates that cause destruction of biomolecules and essential food components (e.g., proteins, astaxanthin, β-carotene, and vitamin A).

In general, the action of LOX in foods is undesirable, particularly the generation of harmful free radicals, the destruction of essential biomolecules like carotenoids and other essential food components that manifest in effects such as gradual color loss in salmonids during frozen storage, and off flavor development in fatty foods. However, LOX is put to some beneficial uses in bread making for the bleaching of flour and for improving the viscoelastic properties of dough. In plants, LOX participate in flavor formation through the formation of the aldehyde 2-hexenal. Some of the aldehyde thus formed may be oxidized to the corresponding carboxylic acid by the enzyme aldehyde dehydrogenase or reduced by alcohol dehydrogenase to the corresponding alcohol. Esters form from the carboxylic acids and alcohols to impart flavors to the plant material.

Peroxidase and Catalase

These are heme iron-containing enzymes that occur naturally in plants, animals, and microorganisms. They use H_2O_2 as coreactant to catalyze the oxidation of other peroxides to form H_2O and oxidized products, such as alcohols. Examples of peroxidases are horseradish peroxidase, glutathione peroxidase, cytochrome c peroxidase, and catalase. Catalase is usually mentioned separately from the rest of the peroxidases as it displays absolute specificity for H_2O_2. In the food industry, thermal inactivation of peroxidases is used as a measure of the efficiency of blanching treatment. Catalase is used for the removal of H_2O_2 from food products (e.g., to remove residual H_2O_2 from cold pasteurization of milk); it is also used in conjunction with GOX

for desugaring eggs and removing head space O_2. Peroxidases may also be used to remove phenolic pollutants from industrial waste waters. However, some other effects of peroxidases in foods are undesirable, such as browning in fruits and off flavors in vegetables.

Xanthine Oxidase

XO is a molybdo-flavoprotein enzyme that is found largely in the milk and liver of mammals, and it catalyzes the oxidation of hypoxanthine and xanthine (breakdown products of nucleic acids) to uric acid.

$$\text{Hypoxanthine} + H_2O + {}^1/_2O_2 \Leftrightarrow \text{Xanthine} + {}^1/_2H_2O_2 \qquad (1)$$

$$\text{Xanthine} + H_2O + {}^1/_2O_2 \Leftrightarrow \text{Uric acid} + {}^1/_2H_2O_2 \qquad (2)$$
It is variously suggested that XO is involved in the spontaneous development of oxidized flavors in raw milks. This defect caused by XO in raw milk may be prevented by treatment with the digestive enzyme trypsin (Lim and Shipe 1972).

Ascorbic Acid Oxidase

Ascorbic acid oxidase (or more precisely, L-ascorbic acid oxidase) catalyzes the oxidation of L-ascorbic acid (vitamin C) to dehydroascorbic acid.

$$2\,\text{L-ascorbate} + O_2 \Leftrightarrow 2\,\text{Dehydroascorbate} + 2\,H_2O$$

The above reaction is important as the presence of the enzyme can lead to the destruction of vitamin C in fruits and vegetables. The same reaction serves as the basis for its use for the enzymatic determination of vitamin C (in fruit juices) and for eliminating the interferences due to the vitamin in clinical analysis. Sources of ascorbic acid oxidase include squash (plant source) and the bacterium *Aerobacter aerogenes*.

Lactate Dehydrogenase

LDH occurs in plants, animals, and microorganisms (e.g., lactic acid bacteria such as *Lactococcus*, *Enterococcus*, *Streptococcus*, *Pediococcus*). LDH catalyzes the interconversions between lactate and pyruvate with the participation of nicotinamide adenine dinucleotide (NAD^+) as hydrogen acceptor (i.e., from lactate to pyruvate) or NADH as hydrogen donor (i.e., in the reverse reaction from pyruvate to lactate).

$$\text{Lactate} + NAD^+ \Leftrightarrow \text{Pyruvate} + NADH + H^+$$

Lactate formed by the enzymes is an essential component of dairy products such as sour milk products, yogurt, ititu, kefir, and cottage cheese. The formation of lactate lowers the pH and promotes curdling of casein in fermented milks; it also contributes to the sour flavor of sourdough breads and is used in beer brewing to lower the pH and add "body" to beer.

In general, the breakdown of body tissues is accompanied by an increase in the levels of LDH, thus LDH levels are used as part of the diagnosis for hemolysis and other health disorders, including cancer, meningitis, acute pancreatitis, and HIV.

Sulfhydryl Oxidase

SO enzymes catalyze the oxidation of thiol groups into disulfides as follows:

$$2RSH + O_2 \rightarrow RS - SR + H_2O_2$$

The enzymes have been described in animal milk (Burgess and Shaw 1983) and egg white (Hoober et al. 1996, 1999, Thorpe et al. 2002), and in microorganisms (de la Motte and Wagner 1987). SO enzymes from bovine milk, pancreas, and kidney have been reported to be Fe dependent (Schmelzer et al. 1982, Sliwkowski et al. 1984, Clare et al. 1988), while others from the small intestine and the skin have been shown to contain Cu^{++} ions (Yamada 1989).

The enzyme has been used in the food industry for flavor control in ultra-high temperature (UHT)-processed milk (Kaufman and Fennema 1987).

TRANSFERASES

The transferases catalyze the transfer of groups from one substrate molecule (donor molecule) to another (acceptor molecule). The reaction is typified by the equation:

$$A–X + B \rightarrow A + B–X$$
where A is the donor and B is the acceptor. Examples include TGases, transglycosidases, transacetylases, transmethylases, and transphosphorylases. Some of them like TGases, and various glucanotransferases (e.g., fructosyl transferase, cyclodextrin glycosyl transferase (CGTase), and amylomaltase), are used extensively in the food industry.

Fructosyl Transferase

Fructosyl transferases catalyze the synthesis of fructose oligomers, also known as fructose oligosaccharides (FOS). The enzymes have been found in plants, e.g., onions (Robert and Darbyshire 1980) and asparagus (Shiomi et al. 1979), and in microorganisms, such as *Streptococcus mutans* (Wenham et al. 1979), *Fusarium oxysporum* (Gupta and Bhatia 1980, 1982), *B. subtilis* (Cheetham et al. 1989, Homann and Seibel 2009), *Aspergillus* spp, *Penicillium* spp, and *Aureobasidium* spp (Prapulla et al. 2000).

Fructo-oligosaccharides account for about 30% of the sweetness of sucrose, but are non-digestible in the gastrointestinal tracts of humans (Oku et al. 1984, Yun et al. 1995), thus they serve as dietary fiber and render the gut milieu more conducive for the growth and proliferation of beneficial intestinal microflora. So, they are applied as low calorie sweeteners and as functional food ingredients with health benefits (Lee et al. 1992). FOS are also used as sugar substitutes in foods such as light jam products, ice cream, and confectionery. The use of FOS in these foods helps to reduce the caloric intake and contributes to a lowering of blood glucose levels and related health issues with diabetes. The enzyme from *B. subtilis* has been used to synthesize fructose disaccharides such as xylsucrose, galactosucrose, and 6-deoxysucrose for use as antigens, in glycosylated

proteins, or as sweeteners or bulking agents in food products (Cheetham et al. 1989).

Cyclodextrin Glycosyl Transferase

CGTase is also known by names like cyclodextrin glucanotransferase and cyclodextrin glucosyltransferase. CGTases have been characterized from various genera of bacteria, including *Bacillus*, *Klebsiella*, *Pseudomonas*, *Brevibacterium*, *Micrococus,* and *Clostridium* (Bonilha et al. 2006, Menocci et al. 2008). CGTases are known to catalyze at least four different reactions; namely coupling, cyclization, disproportionation, and hydrolysis. The most important of these reactions is intramolecular cyclization, whereby linear polysaccharide chains in molecules such as amylose are cleaved, and the two ends of the resulting fragments joined together to produce cyclic dextrins or cyclodextrins or CDs for short. CDs with varying units of glucose that are linked together by $\alpha(1''4)$ glycosidic bonds have been described, namely the 6 glucose CD (or α-CD), the 7 glucose CD (or β-CD), and the 8 glucose CD (or γ-CD). By virtue of their ringed structures, CDs are able to trap or encapsulate other molecules to form inclusion composites with altered physicochemical properties that have great potential for applications in the (functional) foods, cosmetics, and fine chemicals (Shahidi and Xiao-Qing 1993).

Amylomaltase

The enzyme amylomaltase, also known as 4-α-glucanotransferase, catalyzes the transfer of glucans from one α-1,4-glucan to another α-1,4-glucan or to glucose. The amylomaltase enzyme has been found in microorganisms, e.g., *Clostridium butyricum, E. coli, S. pneumonia* (Goda et al. 1997, Pugsley and Dubreuil 1988, Tafazoli et al. 2010) and in plants, e.g., potato (Jones and Whelan 1969, Sträter et al. 2002) and barley (Yoshio et al. 1986). The enzyme acts on both malto-oligosaccharides and amylose to form medium to highly polymerized cycloamyloses that are highly water-soluble (Takaha et al. 1996, Terada et al. 1997). These products are also expected to be of use in the (functional) food, pharmaceuticals, and fine chemical industries.

Transglutaminase

TGases are transferase enzymes that catalyze the acyl transfer reactions between free amino groups furnished by $-NH_2$ groups (e.g., the ε-NH_2 group of lysine) of amino acids and proteins, and the γ-carboxyamide groups of glutamines (Motoki and Seguro 1998). The TGase-assisted acyl transfer results in the extensive formation of strong and resistant covalent bonds between biomolecules like proteins. The products formed invariably have altered properties in terms of mechanical strength and solubility in aqueous systems. This feature of the enzyme is exploited in commercial food processing to improve the texture of gluten-free breads for individuals suffering from celiac disease (Moore et al. 2004, 2006), for making imitation crab-

meat and fish balls, and for binding small pieces of meat into larger chunks of meat. The enzyme is also used as a binding agent to improve the physical qualities (e.g., texture, firmness, and elasticity) of protein-rich foods such as surimi or ham, and emulsified meat products, such as sausages and hot dogs. They are also used to improve the texture of low-grade meats such as the so-called pale, soft, exudative meat or PSE meats; to improve the consistency of dairy products (milk and yogurt) to make them thicker and creamier; and to make noodles firmer (Kim and Kim 2009). TGases have been found to be present in animals (e.g., threadfin bream, big-eye snapper, white croaker (Benjakul et al. 2010), guinea pig (Huang et al. 2008), in birds, amphibians, and invertebrates (Lantto et al. 2005), and in plants and microorganisms (e.g., *Bacillus*, *Streptoverticullium,* and *Streptomyces* spp (Yokoyama et al. 2004).

PROTEASES

The term protease is used to represent the group of enzymes that catalyze the cleavage of peptide bonds in proteins and peptide molecules with the participation of water as co-reactant. Other names for this group of enzymes include proteinases or proteolytic enzymes. The majority of industrial enzymes currently in use are proteases, and it is estimated that they constitute about 40% of the total global enzyme production and use (Layman 1986, Godfrey and West 1996). These enzymes are used in the food processing, animal feed, detergent, leather and textiles, photographic, and other industries (Kalisz 1988). Proteolytic enzymes are also used as a digestive aid to facilitate digestion and use of proteins by some people who otherwise cannot readily digest these molecules.

On the basis of their mode of action on the protein/peptide molecules, proteases are classified as either endopeptidases (or endoproteases) or exopeptidases (or exoproteases). Endopeptidases are those proteases that cleave peptide bonds randomly within protein molecules to result in smaller peptides. Examples include trypsin, chymotrypsin, pepsin, chymosin, elastase, and thermolysin. Exopeptidases cleave peptide bonds by successively removing terminal amino acid residues to produce free amino acids and the residual polypeptide molecule. Thus, two types of exoproteases are distinguished, the carboxypeptidases, that is, those that cleave amino acids at the carboxyl or C-terminal of the protein or polypeptide molecule, and the aminopeptidases that cleave amino acids from the amino or N-terminal of the molecule. Examples of carboxypeptidases include depeptidase, cathepsin A, cathepsin C, metallo-carboxypeptidases (e.g., carboxypeptidases A, A2, B, and C), and angiotensin-converting enzyme; examples of aminopeptidase are glutamyl aminopeptidase (a.k.a. aminopeptidase A), arginyl aminopeptidase (also known as aminopeptidase B), alanine aminopeptidase, leucine aminopeptidase, and the methionine aminopeptidases 1 & 2 (also known as METAP 1 & 2).

Proteases are traditionally classified into four sub-groups based on the nature of their active sites as acid, serine, sulfhydryl, and metallo-proteases. Their distinctive features are summarized in the following subsections.

Acid Proteases

The acid proteases (also known as aspartate proteases) are so called because the enzymes in this group tend to have one or more side chain carboxyl groups from aspartic acid as essential component(s) of their active sites, and they are optimally active within the acid pH range. Examples include pepsins, chymosins, rennets, gastricins (from animal sources), cyprosin, and cardosin (from plant sources), and several other aspartic acid proteases from microorganisms such as *Rhizomucor miehei*, *R. pusillus*, *R. racemosus*, *Cryphonectria parasitica*, and *A. niger* (Mistry 2006). Most of the known acid proteases are inhibited by the hexapeptide pepstatin. The major food industry use of acid proteases is in dairy processing, such as for the milk coagulation step in cheese making. In cheese making, the acid proteases added (e.g., rennet of chymosin) act to cleave critical peptide bonds between phenylalanine and leucine residues in κ-casein of the milk to form micelles that aggregate and precipitate out as the curd. The characteristic specificity of these proteases in these dairy products is important to restrict hydrolysis to the peptide bonds between the critical phenylalanine and leucine residues in κ-casein; otherwise, excessive proteolysis could elicit undue texture softening, bitterness, and/or "off-odors" in the product(s).

Serine Proteases

The serine proteases are the most abundant group of the known proteases (Hedstrom 2002). The characteristic features of this group of enzymes include the presence of a seryl residue in their active sites, as well as a general susceptibility to inhibition by serpins, organophosphates (e.g., di-isopropylphosphofluoridate), aprotinin (also known as trasylol), and phenyl methyl sulfonyl fluoride. Examples of the animal serine proteases are chymotrypsin, trypsin, thrombin, and elastase; examples of plant serine proteases are cucumisin (from melon; Kaneda and Tominaga 1975), macluralisin, and taraxilisin (from the osage orange fruit and dandelion, respectively; Rudenskaya et al. 1995); and examples of microbial serine proteases are proteinase K and subtilisin A (Couto et al. 1993). Several of the serine proteases function optimally within neutral to alkaline pH range (pH 7–11), and they find extensive use in the food and animal feed industries. They are used to produce highly nutritive protein hydrolysates from protein substrates such as whey, casein, soy, keratinous materials, and scraps from meat processing, as well as from fish processing discards; for the development of flavor during ripening of dairy products; and for the production of animal fodder from keratinous waste materials generated from meat and fish processing (Dalev 1994, Wilkinson and Kilcawley 2005). Other industrial applications of serine proteases include their use for the regioselective esterification of sugars, resolution of racemic mixtures of amino acids, and production of synthetic peptides to serve as pharmaceutical drugs and vaccines (Chen et al. 1999, Guzmán et al. 2007, Barros et al. 2009). Serine proteases are also used commercially for the treatment and bating of leather to remove undesirable pigments and hair from leather (Valera et al. 1997, Adıgüzel et al. 2009). They are also used for the treatment of industrial effluents and household waste, to lower the biological oxygen demand, and viscosity, to increase the flow properties of solid proteinaceous waste (e.g., feather, hair, hooves, skin, and bones), as well as wastewater from animal slaughterhouses and fish processing plants (Dalev and Simeonova 1992). Serine proteases also find some use in the degumming and the detergent industries (Godfrey and West 1996), and in medicine for the treatment of burns, wounds, and abscesses (Lund et al. 1999).

Sulfhydryl Proteases

The sulfhydryl (also known as thiol or cysteine) proteases are so called because they contain intact sulfhydryl groups in their active sites and are inhibited by thiol reagents such as alkylating agents and heavy metal ions. Examples include plant types like actinidain, papain, bromelain, chymopapain, and ficin; animal types like cathepsins B and C, calpains, and caspases; and clostripain, protease 1 and others from various microorganisms such as *Streptococcus* sp (Whitaker 1994), thermophilic *Bacillus* sp (Almeida do Nascimento and Martins 2004), and *Pyrococcus* sp (Morikawa et al. 1994). The activities of this group of enzymes are enhanced by dithiothreitol and its epimer dithioerythritol, cysteine, and 2-mercaptoethanol, and they are inhibited by compounds such as iodoacetate, *p*-chloromercuribenzoic acid, cystatin, leupeptin, and *N*-ethylmaleimide. The enzymes in this group tend to be optimally active around neutral pH (i.e., pH 6–7.5) and are relatively heat stable, which accounts for their use in meat tenderizers. Thiol proteases act to degrade myofibril protein and collagen fibers to make meats tender. Meat tenderness is a very important factor in meat quality evaluation. Ficin tends to have the greatest effect on myofibril protein hydrolysis due to its relatively higher thermal stability and broader specificity, followed by bromelain and papain in that order, although bromelain tends to degrade collagen fibers more extensively (Miyada and Tappel 1956). In commercial application, papain and bromelain are more frequently used because the higher hydrolytic capacity of ficin often results in excessive softening and mushiness in the treated meat (Wells 1966). These proteases may be applied in various ways to achieve meat tenderization, as by blending, dipping, dusting, soaking, spraying, injection, and vascular pumping (Etherington and Bardsley 1991). A common drawback with most of these approaches is the unequal distribution of the enzyme that could result in excessive tenderization or inadequate tenderization of different parts of the meat. The problem of uneven distribution of the enzyme may be minimized by using an additional tumbling step after enzyme treatment to increase distribution or by pre-slaughter injections of the animal with the enzyme (Beuk et al. 1962, Etherington and Bardsley 1991).

Sulfhydryl proteases are also used in the brewing industry to control haziness and improve clarity of the beverage. Haziness may form in the product during the aging process via aggregation of larger peptide and polyphenol molecules to form high molecular weight complexes. This is particularly enhanced during chilling of the beer, where solubility is minimal, and this group of enzymes is also used in the baking industry to improve the stretchability and firmness of the dough, through the

modification of gluten. The enzymes are able to do this by increasing the viscoelastic, gas-retaining, and thermosetting properties of the dough. The action of these enzymes results in benefits such as shorter time of mixing, better flow, improved shaping, and increased gas retention of the flour or dough (Mathewson 1998).
Metalloproteases

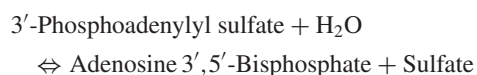
The term metalloproteases is used to encompass those proteases that have metal ions in their active sites. These enzymes typically require an essential metal ion (e.g., Ni^{2+}, Mg^{2+}, Mn^{2+}, Ca^{2+}, Zn^{2+}, and Co^{2+}) for functional activity. Urease is an example of the nickel (Ni^{2+})-containing metalloenzymes. It catalyzes the breakdown of urea into carbon dioxide (CO_2) and ammonia (NH_3). The urease-catalyzed reaction occurs as follows:

$$(NH_2)_2\,CO + H_2O \rightarrow CO_2 + 2NH_3$$
The NH_3 thus produced functions to neutralize gastric acid in the stomach. Urease is found in bacteria, yeast, and several higher plants. The major sources of urease include the Jack bean (*Canavalia ensiformis*) plant and the bacteria *B. pasteurii*. The enzyme is also found in large quantities in soybeans and other plant seeds, in certain animal tissues (e.g., liver, blood, and muscle), in intestinal bacteria (e.g., *Eubacterium aerofaciens*, *E. lentum,* and *Peptostreptococcus productus*), and in yeasts (e.g., *Candida curvata, C. humicola, C. bogoriensis, C. diffluens,* and *Rhodotorula* and *Cryptococcus* species), as well as the blue-green algae (*Anabaena doliolum* and *Anacystis nidulans*). Examples of the metalloproteases that are Mg^{2+} dependent include inorganic diphosphatase that catalyzes the cleavage of diphosphate into inorganic phosphates, that is,

$$\text{Diphosphate} + H_2O \Leftrightarrow 2\,\text{Phosphate}$$
and phosphatidylinositol triphosphate 3-phosphatase that catalyzes the hydrolysis of phosphatidylinositol 3,4,5-trisphosphate, that is,

$$\text{Phosphatidylinositol 3,4,5-trisphosphate} + H_2O$$
$$\Leftrightarrow \text{Phosphatidylinositol 4,5-bisphosphate} + \text{Phosphate}$$

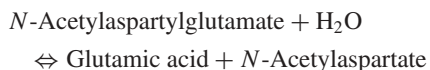
An example of metalloproteases containing manganese (Mn^{2+}) metal ions is phosphoadenylylsulfatase, which participates in sulfur metabolism and catalyzes the hydrolytic cleavage of 3′-phosphoadenylyl sulfate into adenosine 3′,5′-bisphosphate and sulfate:

$$\text{3′-Phosphoadenylyl sulfate} + H_2O$$
$$\Leftrightarrow \text{Adenosine 3′,5′-Bisphosphate} + \text{Sulfate}$$


A well-known calcium (Ca^{2+})-containing metalloprotease is lactonase, which hydrolyzes lactones into their corresponding hydroacids, that is,

$$\text{Lactone(s)} + H_2O \Leftrightarrow \text{4-Hydroxyacid(s)}$$
The enzyme lactonase also participates in the metabolism of galactose and ascorbic acid.

Other metalloproteases contain zinc (Zn^{2+}) metal ions, e.g., glutamate carboxypeptidase and glutamyl aminopeptidase. Glutamate carboxypeptidase catalyzes the hydrolysis of *N*-acetylaspartylglutamic acid into glutamic acid and *N*-acetylaspartate as shown in the following reaction:

$$N\text{-Acetylaspartylglutamate} + H_2O$$
$$\Leftrightarrow \text{Glutamic acid} + N\text{-Acetylaspartate}$$


while glutamyl aminopeptidase (also known as aminopeptidase A) catalyzes the hydrolysis of glutamic and aspartic acid residues from the N-termini of polypeptides, e.g.,

$$\text{Aspartic acid-polypeptide} + H_2O$$
$$\Leftrightarrow \text{Aspartic acid} + \text{Polypeptide}$$
Glutamyl aminopeptidase is important because of its capacity to degrade angiotensin II into angiotensin III, which promote vasoconstriction and high blood pressure. Both glutamate carboxypeptidase and glutamyl aminopeptidase are present in membranes. Another important Zn^{2+}-containing metalloprotease is the *insulin-degrading enzyme* that is found in humans and degrades short chain polypeptides such as the β-chain of insulin, glucagon, transforming growth factor, and endorphins. Collagenases are also Zn^{2+} dependent and they act to break down the peptide bonds in collagen. Cobalt (Co^{2+})-containing metalloproteases include methylmalonyl coenzyme A mutase that converts methyl malonyl-CoA to succinyl-CoA, which is involved in the extraction of energy from proteins and fats; other Co^{2+}-containing metalloenzymes are methionine aminopeptidase and nitrile hydratase (Kobayashi and Shimizu 1999).

Sources of metalloproteases include those derived from animals, like carboxypeptidases A and B, collagenases, gelatinases, and procollagen proteinase; microbial ones such as thermolysin, lysostaphin (from *Staphylococcus* sp), acidolysin (from *Clostridium acetobutylicum*), and neutral metalloproteases (from *Bacillus* sp); as well as plant types like the zinc-dependent endoproteases in the seeds of grass pea (*Lathyrus sativus* L.). Agents or substances that are capable of binding or interacting with the catalytic metal ions tend be potent inhibitors of this group of enzymes. Examples of these inhibitors include phosphoramidon, ethylenediaminetetraacetic acid (EDTA), methylamine, vitamin B-12, dimercaprol, porphine, phosphonates, and 1,10-phenanthroline.

Common commercially available metalloenzymes are Neutrase (Novo Nordisk 1993) and Thermoase (Amano Enzymes) and some of the industrial applications of metalloenzymes include the synthesis of peptides for use as low calorie sweetener and drugs for the food and pharmaceutical industries, respectively. Thermolysin and vimelysin (from *Vibrio* sp) are both used for the synthesis of aspartame (Murakami et al. 1998); in this regard, vimelysin is superior to thermolysin for synthesis of the dipeptide at low temperatures. The metalloprotease thermolysin is also used in combination with other proteases (protease cocktails) for the production of food protein hydrolysates and flavor-enhancing peptides and for accelerating the ripening of dry sausages (Fernandez et al. 2000). They are also used for the hydrolysis of slaughterhouse waste, and in the brewing industry to facilitate filtration of beer and production of low calorie beers.

Carbohydrases

Carbohydrases are a group of enzymes that catalyze the hydrolysis or synthesis of polysaccharides. Examples include the amylases that hydrolyze starch molecules, maltases that break down maltose into glucose units, and lactases that degrade lactose into galactose and glucose. Other examples include invertases that hydrolyze sucrose into glucose and fructose, glucanases that catalyze the hydrolysis of glucans, cellulases that break down celluloses into low molecular weight cellodextrins, cellobiose, and/or glucose. Carbohydrases are ubiquitous in nature and are widespread in animals, plants, and microorganisms. For example, the amylases, pectinases, chitinases, and β-galactosidases are all found in plants, animals, and microorganisms (bacteria, fungi, and yeast). Microbial sources of commercially available carbohydrases are bacteria (e.g., *B. licheniformis*), various fungi (e.g., *A. niger*, *A. oryzae*, *A. aculeatus*, *Trichoderma reesei*), and yeasts (e.g., *Kluyveromyces lactis*, *Saccharomyces cerevisiae*). They are also present in algae, e.g., marine algae.

Two types of carbohydrases may be distinguished based on their modes of action as the endo- versus exo-carbohydrases. The endo-hydrolases (e.g., α-amylase) catalyze the cleavage of the internal glycosidic bonds of carbohydrate molecules, while the exo-hydrolases (e.g., β-amylase) catalyze the hydrolysis of carbohydrates by removing the maltose units from the nonreducing end of complex carbohydrate molecules. Carbohydrases may also be classified into the starch-hydrolyzing types and the nonstarch-hydrolyzing types. The starch-hydrolyzing carbohydrases (amylases, glucanases) act on amylose and amylopectin, and their principal applications are in the production of glucose syrups, ethanol, as well as in baking and brewing. The nonstarch-hydrolyzing carbohydrases are those that break down polymers of hexoses other than amylose and amylopectin, e.g., cellulases, lactases, maltases, galactosidases, pectic enzymes, invertases, chitinases, and fructosidases.

Amylases, Glucanases, and Pullulanases

Some of the more common carbohydrases and their uses in the food industry are the amylases that are used in the starch, alcoholic beverages, and the sugar industries. For example, Novozymes produces a heat-stable α-amylase (known as termamyl) from a genetically modified strain of *B. licheniformis* for the continuous liquefaction of starch at high temperatures (105–110°C). This same heat-stable enzyme is used to liquefy or "thin" starch during brewing and mash distillation. It is also used in sugar manufacture to hydrolyze the starch in sugar cane juice. Nonfood applications of α-amylases include their use in the textiles industry for de-sizing of fabrics and in detergent formulations for the removal of starch-based stains from fabrics. Amyloglucosidase (AMG) is a type of amylase that cleaves the α-1,4- and α-1,6-glycosidic bonds and removes glucose units from liquefied starch sequentially. The commercially available AMG enzyme is derived from a strain of the fungus *A. niger*, and it is used to produce sugar syrups from starches and dextrins.

Glucanases are a group of hydrolytic enzymes that catalyze the cleavage of glucans into various glucose oligomers, trisaccharides (e.g., maltotriose and nigerotriose), disaccharides (e.g., maltose, trehalose, and cellobiose), and the monosaccharide glucose. The term glucans encompasses those carbohydrate compounds made up of repeating glucose units linked together by glycosidic bonds. Examples of glucans include amylose starch (with α-1,4-glycosidic bonds), cellulose (β-1,4-glycosidic bonds), zymosan (β-1,3-glycosidic bonds), glycogen (with both α-1,4- and α-1,6-glycosidic bonds), amylopectin starch (with both α-1,4- and α-1,6-glycosidic bonds), and pullulan (with both α-1,4- and α-1,6-glycosidic bonds). They occur in plants, animals, and microorganisms; in plants and fungi, in particular, they serve as structural, defense, and growth functions, and as storage forms of chemical energy (Thomas et al. 2000).

Several microorganisms (fungi, bacteria (Kikuchi et al. 2005), and yeasts (Abd-El-Al and Phaff 1968) produce glucanases that enable them to digest glucans for use as nutrients and energy source. Glucanases are also widespread in plants, e.g., in seed plants (Elortza et al. 2003), rice (Thomas et al. 2000), tobacco (Leubner-Metzger 2003), acacia (González-Teuber et al. 2010), and in animal tissues, e.g., the embryo of sea urchins (Bachman and McClay 1996), nematodes (Kikuchi et al. 2005), mollusks (Kozhemyako et al. 2004), crayfish (Lee et al. 1992), earthworms (Beschin et al. 1998), shrimp (Sritunyalucksana et al. 2002), and insects (Hrassnigg and Crailsheim 2005). Bacteria are used industrially to produce glucanases for use in applications such as brewing to break down glucans in barley, thereby facilitating filtration and preventing clogging of filters.

Pullulanase (also known as "debranching enzyme") is a specific glucanase that degrades pullulan, a carbohydrate made up of repeating units of the trisaccharide maltotriose linked together by α-1,6 glycosidic bonds. Depending on the nature of the glycosidic bond cleaved, two types of pullulanases are distinguished. The type I pullulanases cleave the α-1,6 bonds, while the type II pullulanases hydrolyze both the α-1,4 and α-1,6 linkages. Pullulanases are produced by bacteria (e.g., *B. cereus* (Nair et al 2006) and *Klebsiella* sp. (Pugsley et al. 1986)), and they are also found in plants (e.g., rice (Yamasaki et al. 2008), wheat (Liu et al. 2009), maize (Dinges et al. 2003)).

By virtue of their capacity to break down glucans into glucose and low molecular weight oligomers of glucose, glucanases and pullulanases are used extensively in industry for the manufacture of animal feeds, alcoholic (beer and wine) and nonalcoholic beverages (tea, fruit pulps), baked goods (breads), leather, and textiles, as well as for waste treatment, oil extraction, and in detergents.

Various amylase mixes are used as multienzyme cocktails, which are employed to hydrolyze carbohydrates. An example is the product Viscozyme, produced and marketed by Novozymes from the fungus *A. aculeatus*. Viscozyme is used widely in the food industry to degrade nonstarch polysaccharides, including branched pectin-like substances often associated with starch in plant materials, thereby reducing the viscosity of such materials to facilitate the extraction of useful products from plant materials. This way, the enzyme can also make starches more readily available for fermentation into various liquefied products.

Other carbohydrases available under various trade names for food uses include a fungal amylase powder derived from *A.*

oryzae known as asperzyme and a liquid saccharifying amylase for the production of fermentable sugars known as adjuzyme, which is derived from *A. niger*. An Enzeco glucoamylase powder derived from *A. niger* is also commercially available for use in baked goods to improve proofing in lean or frozen doughs, and brewers amylase produced in powder form from *Aspergillus sp* and *Rhizopus oryzae* is used for the manufacture of light beers. Others are Brewers Fermex derived from *Aspergillus sp.* and *Rhizopus oryzae* in powder form for use in increasing the fermentability of wort and cookerzyme derived from *B. subtilis* for accelerated hydrolysis of starch adjuncts.

Galactosidases and Lactases

Galactosidases are those carbohydrases that catalyze the hydrolysis of galactosides such as lactose, lactosylceramides, ganglioside, and various glycoproteins into their constituent monosaccharide units. Two types of galactosidases are distinguished based on their mode of action as α- and β-galactosidases. The α-galactosidases (also known as α-gal) catalyze the hydrolytic cleavage of the terminal α-galactosyl residues from α-galactosides (including certain glycoproteins and glycolipids) and they can catalyze the hydrolysis of the disaccharide melibiose into galactose and glucose. α-Gal is used as a dietary supplement (e.g., beano) to facilitate the breakdown of complex sugars into simpler forms to permit easier digestion and reduce intestinal gas and bloating. The enzyme may also be used to reduce the complex carbohydrate content of the beer to increase the simple sugar content and hence the alcohol content of beer. The β-gals facilitate the hydrolysis of β-galactosides such as lactose, various glycoproteins, and ceramides into simpler forms.

Lactases belong to the β-galactosidase family of enzymes; they catalyze the breakdown of the milk sugar lactose into its constituent monosaccharides, galactose and glucose units, that is,

Lactose + H_2O ⇔ Galactose + Glucose

Lactases are produced in commercial quantities from yeasts such as *K. fragilis* and *K. lactis,* and from fungi such as *A. niger* and *A. oryza* (Mustranta et al. 1981). Other lactase-producing microorganisms include the bacteria *Streptococcus cremoris*, *Lactobacillus bulgaricus,* and *Leuconostoc citrovorum* (Ramana Rao and Dutta 1978). Lactases are also found in the mucous lining of the small intestines of cows and rabbits, and in the walls of the small intestines of humans from as early as the fifth month of intrauterine life. However, lactase levels tend to be higher in younger animals and human infants, and the levels generally decrease with age (Heilskov 1951). The enzyme is also found in plants, e.g., from the calli and roots of gherkin, pea, poppy, and eastern blue star seedlings (Neubert et al. 2004).

Lactase is commercially produced by Novozymes from the dairy yeast *K. lactis* and marketed as Lactozym. Lactase as lactozym is widely used in the dairy industry to produce fermented milks, ice-cream, milk drinks, and lactose-reduced milk for people who are lactose-intolerant and for household pets (e.g., cats) that cannot utilize lactose. Milks treated with lactose tend to be sweeter than their untreated counterparts because the monosaccharides glucose and galactose produced in the treated milks are sweeter than the disaccharide lactose in untreated milks. Crystallization of lactose in condensed milk can also be prevented by treating the milk first with lactase. Lactase-treated milks used for the preparation of cultured milk products (e.g., cottage cheese or yogurt) ferment faster than untreated milks, because lactose in the latter ferment at a slower pace than the glucose and galactose in the treated milks. As well, the cultured milk products from the lactase-treated milks tend to be sweeter than the products prepared from the nontreated milks. Milk whey may also be treated with lactase and concentrated to form syrups for use as a sweetener in food products. Ice cream made from lactase-treated milk (or whey) also has little or no lactose crystals, thus the undesirable "sandy" feel due to lactose crystallization is averted.

Maltases

Maltase is the carbohydrase that breaks down the disaccharide maltose into glucose units as summarized in the reaction below:

Maltose + H_2O ⇔ 2 α-Glucose
Maltase is found in humans and other vertebrate animals, plants, and microorganisms (bacteria and yeast). In humans, digestion of starch commences in the mouth with ptyalin (saliva enzyme) and pancreatic amylases breaking down the starch into maltose. The maltose is subsequently hydrolyzed by intestinal maltase into glucose for utilization by the body to produce energy or for storage in the liver as glycogen. Maltase (from barley malt) is used in brewing to increase the glucose content for conversion into alcohol. Maltase from *A. oryzae* is used in the beet-sugar and molasses distilleries, and in the industrial production of glucose syrups (McWethy and Hartman 1979).

Cellulases

Cellulases are enzymes that potentiate the breakdown of the β-1,4-glycosidic bonds in cellulose. They are produced commonly by bacteria (e.g., *Clostridium thermocellum*, *Acidothermus cellulolyticus* (Tucker et al. 1988)), fungi (*Trichoderma reesei*, *T. hamatum*, *Fusarium roseum*, *Curvularia lunata* (Sidhu et al. 1986)), and protozoa (e.g., *Trichomitopsis termopsidis* (Odelson and Breznak 1985), *Eudiplodinium maggii*, *Epidinium ecaudatum caudatum,* and *Ostracodinium obtusum bilobum* (Coleman 1985)), although the enzymes are also found in plants (e.g., cress and pepper (Ferrarese et al. 29)) and animals (e.g., termites, crustacea, insects, and nematodes (Watanabe and Tokuda 2001)). A simplified equation for the hydrolysis of cellulose by cellulases may be summarized as

Cellulose + H_2O ⇔ nβ-D-Glucose
Native cellulose is highly crystalline in nature and its complete hydrolysis entails stepwise reactions catalyzed by a complex of cellulase enzymes. It entails the preliminary unraveling of the crystalline cellulose molecules into simple (or linear) cellulose chains by endocellulases. The linear cellulose chains

then serve as substrates for exocellulases to produce smaller oligosaccharides (such as cellobiose and cellotetrose), and the latter molecules are hydrolyzed further by cellobiases into β-D-glucose units.

Cellulase is used in coffee processing to hydrolyze cellulose during drying of the beans. They are also used extensively in laundry detergents, in textile, pulp, and paper industries, as digestive supplements in pharmaceutical applications, and to facilitate in the biotransformation of feedstock into biofuels, although this process is presently in its infancy. The enzyme is marketed commercially as *Celluclast* by Novozymes and is used to digest cellulose into fermentable sugars in the form of glucose oligomers, cellobiose, and glucose, or to reduce the viscosity of soluble cellulosic materials.

Invertases and Sucrases

Invertases, also known as β-fructofuranosidases, are enzymes that hydrolyze the disaccharide sucrose into its corresponding monosaccharide units, fructose and glucose, that is,

Sucrose + H_2O ⇔ Fructose + Glucose

Sucrases also spilt sucrose into equimolar mixtures of glucose and fructose, the difference between the two being that invertases split the O–C (fructose) bond, while sucrases break the O–C (glucose) bond. The equimolar mixture of glucose and fructose thus produced is known as invert sugar or artificial honey. Invertase is produced for commercial use from the yeast *S. cerevisiae* or *S. carlsbergensis*, although bees also synthesize the enzyme to make honey from nectar. The enzymes are also present in bacteria (Bogs and Geider 2000), in the cell walls and vacuoles of higher plants like carrots (Quiroz-Castaneda et al. 2009), tomatoes (Elliot et al. 1993), as well as in the seeds, stems, roots, and tubers of several higher plants (Cooper and Greenshields 1961, 1964).

Invertase is produced and marketed commercially under the brand name Maxinvert by Novozymes and is used extensively in the confectionery industry to make products such as chocolate-covered berries and nuts, soft-centered candies, marshmallows, and fudges. Invertase derived from yeast is also commercially available from Enzeco for the inversion of sucrose into a mixture of fructose and glucose.

Pectinases

Pectinase or pectic enzymes are a group of carbohydrases that hydrolyze pectins, large and complex heteropolysaccharides comprising of 1,4-α-D-galactosyluronic acid residues. Pectins occur naturally in fruits and can contribute to the viscosity and haziness of alcoholic and nonalcoholic beverages. Pectic enzymes act to break down pectins into smaller molecules to enhance their solubility. By this action, pectic enzymes clear hazes in beverages that form from residual pectins in the juices and also increase the yields of fruit juices. Members of the pectinase family of enzymes include pectinesterase (also known as pectyl hydrolase, pectin methyl esterase, or PME) and polygalacturonase. They are widespread in the cell walls of higher plants (e.g., avocado, carrots, tomato), as well as in some bacteria (e.g., *B. polymyxa*, *Closytidium multifermentans,* and *Erwina aroideae*), fungi (e.g., *A. niger*, *Penicillium digitatum, Geotricum candidum,* and *Fusarium oxysporum*), and yeasts (e.g., *S. fragilis*). PME catalyzes the hydrolysis of pectins via the removal of methoxyl groups to form pectic acids, that is:

Pectin + H_2O ⇔ Pectic acid + Methanol

Pectin lyase also known as pectolyase hydrolyzes pectins via eliminative cleavage of (1,4)-α-D-galacturonan methyl esters in pectins with 4-deoxy-6-*O*-methyl-α-D-galact-4-enuronosyl residues at the nonreducing termini. Food-grade pectolyase is produced on a commercial scale from fungi and is used to remove residual pectins in wines and ciders. The enzyme is also used in combination with cellulase in plant cell culture to degrade plant cell walls to generate protoplasts.

Polygalacturonases (PGases) break down the glycosidic bonds linking the galacturonic acid residues in the polymer, and they may be either endo or exo in action. The endo-PGases cleave the 1,4-α-D-galactosyluronic acid residues of pectins in a random fashion, while the exo-PGases degrade pectins by terminal action to produce galacturonic acid residues.

A variety of pectic enzymes are commercially available from Novozymes for applications in the food industry. Examples include Pectinex (a mixture of pectinases produced from *A. niger*) for fruit and vegetable juice processing and the maceration of plant tissues, Peelzym (produced from *A. aculeatus*) for hands-free peeling of citrus fruits, and NovoShape (produced from *A. aculeatus* and *A. oryzae*) for maintaining the shape and structure of whole chunks or pieces of fruits in a finished product.

Fructosidases

Fructosidases, also known as inulases, are a group of enzymes that catalyze the hydrolysis of inulin or fructans into simpler components. Inulin is a linear polysaccharide naturally present in plants. The linear chains consist of about 35 fructose molecules linked together by β-1,2-glycosidic bonds and terminating in a glucose unit. Interest in this group of enzymes has been growing in recent years because of their capacity to form industrial fructose from fructans. These enzymes are commonly found in plants and are also produced by microorganisms such as *Aspergillus* sp., *S. fragilis,* and *S. marxianus*. Fructosidases produce fructose from inulin in high yield for commercial use (Singh et al. 2007, Sirisansaneeyakul et al. 2007, Muñoz-Gutiérrez et al. 2009).

LIPASES

The term lipases is used to refer to a large group of hydrolytic enzymes that catalyze the breakdown of ester bonds in biomolecules such as triglycerides (TGs), phospholipids, cholesterol esters, and vitamin esters. On the basis of the nature of their substrate molecules, lipases are classified into triacylglycerol lipase (or true lipases), phospholipases, sterol esterase, and retinyl-palmitate esterase. For TGs, arguably the most abundant food lipids, lipases hydrolyze the ester bonds in TGs to form free fatty acids and glycerol. Lipases belong to the α/β

hydrolase family of enzymes that are characterized by a particular α-helix and β-structure topology, that is, a fan-like pattern of the central β-sheets, and also include esterases, thioesterases, and several other intracellular hydrolases. The catalytic triad of the α/β hydrolase proteins consists of a nucleophilic serine residue, an aspartic or glutamic acid residue, and a histidine group and differs from the catalytic triad in serine proteases only in the sequence in which the amino acids in the triad occur (Wang and Hartsuck 1993, Wong and Schotz 2002). Homologous lipases exhibit subtle differences from one another, and four major types are distinguished based on structural, functional, or sequence homologies: (i) the consensus sequence GxSxG around the active site serine, where x can be any amino acid, (ii) those with the strand-helix motif also around the active site serine; (iii) those with a buried active site covered by a region known in different lipases as active site loop, lid domain, or flap, and (iv) those with the order of the catalytic triad residues Ser . . . Asp/Glu . . . His (Carriere et al. 2000, Svendsen 2000, Hui and Howles 2002).

Lipase Specificity, Mechanism of Action, and Some General Properties

There are several categories of lipase specificity. Fatty acid-specific lipases tend to prefer specific fatty acids or classes of fatty acids (e.g., short-chain, polyunsaturated, etc.). Some lipases exhibit positional specificity and are regioselective in discriminating between the external, primary (*sn*-1 and *sn*-3 positions), and internal, secondary (*sn*-2 position), ester bonds. For example, several lipases of microbial origin, as well as gastric and phospholipases, show a preference for the external ester bonds; some exhibit partial stereospecificity, that is, a preference for either *sn*-1 or *sn*-3 position of TG, and some others exhibit enantioselectivity and can differentiate between enantiomers of chiral molecules (Anthonsen et al. 1995, Hou 2002).

The most accepted kinetic model of lipase activity is that the lipase exists in both the active and inactive conformation in solution. In aqueous solutions, the inactive conformation is predominant, thus the enzyme activity is low. However, at the lipid–water interface, the active conformation is favored, and water-insoluble substrates are hydrolyzed by the enzyme. The active forms of the enzyme in solution that are adsorbed at the interface may have different conformations (Martinelle and Hult 1995). Interfacial activation of lipases is well documented. Excess substrate induces a drastic increase in lipase activity, while esterases display a hyperbolic, Michaelis–Menten relationship between the enzyme activity and substrate concentration, lipases show a sigmoidal response (Anthonsen et al. 1995). Binding of lipase to the emulsified substrate at the lipid–water interface elicits a conformational change that greatly enhances its catalytic activity: the lid domain flips backwards to expose the active site; as well, the β5 loop orients in a way to enhance access of the substrate to the enzyme's active site.

Lipases are water-soluble proteins; nonetheless, their substrates are water-insoluble. Pancreatic lipases have the following features: temperature optima around 37°C and thermal stabilities up to approximately 50°C (Gjellesvik et al. 1992), and pH optima in the range of 6.5–8.5 and pH stabilities between pH 6 and 10 (Wang and Hartsuck 1993). The molecular weights range between 45 and 100 kDa (Wong and Schotz 2002, Wang and Hartsuck 1993), and they are anionic with isoelectric points typically ranging from 4.5 to 7 under physiological conditions (Armand 2007). They are inhibited by organophosphorous compounds like di-isopropyl fluorophosphates via irreversible phosphorylation of active site serine. High concentrations of both cationic (e.g., quaternary ammonium salts) and anionic (e.g., SDS) surfactants also inhibit lipase activity. Other inhibitors of lipases include metal ions (e.g., $Fe^{2+/3+}$ and mercury derivatives). Calcium and zinc ions may either activate lipases or produce no effect (Patkar and Bjorkling 1994, Anthonsen et al. 1995).

Conventional Sources of Lipases—Mammalian, Microbial, and Plant

The pancreas and serous glands of ruminants, especially young calf and lamb, and the pancreas of pigs have served as important sources of lipases for flavor development in dairy products for quite some time now. In subsequent years, microbial lipases have received most of the attention in lipase research and have been considerably exploited in numerous applications as a consequence of the relative ease of their production and genetic manipulation, as well as the wider range in properties. Microbial lipases constitute the most significant commercially produced lipases.

Lipases have also been sourced from plants. However, there is a dearth of information on plant lipases compared to mammalian and microbial lipases. Plant lipases thus far characterized include the triacylglyceride lipases, various phospholipases, as well as glycolipase and sulpholipase. The appeal of plant lipases derives from their unique capacity to cleave all three fatty acids from TGs (e.g., as shown by oat lipase) and their distinct substrate specificities and abilities to synthesize "structured lipids" (as demonstrated with rape-seed lipase that esterifies fatty acids to primary alcohols exclusively). Several distinctive features of plant lipases have been imputed to phospholipases, such as the use of phospholipase D from cabbage to synthesize phosphatidylglycerols for use as an artificial lung surfactant. In food processing and preservation, an understanding of the properties of plant lipases is crucial for maintaining quality and freshness, particularly in oilseeds, cereals, and oily fruits, and for the production of high-quality edible oils (Mukherjee and Hills 1994, Mukherjee and Kiewit 2002).

Phospholipases are a broad class of enzymes catalyzing mainly water-insoluble substrates and are involved in digestive, regulatory, and signal transduction pathways, among others. Their nomenclature (phospholipase A_1, A_2, B, C, and D) is based on which phospholipid ester bond they attack. The majority of these enzymes require Ca^{2+} for (maximal) catalysis, have many disulfide bonds, and are relatively small with molecular weights ranging from 13 to 30 kDa, but there are few above 80 kDa (Lopez-Amaya and Marangoni 2000a). The amino acid sequences of most phospholipases are totally different from those of TG lipases (Svendsen 2000). Like lipase activity, phospholipase activity has also been associated with the

deterioration of seafood postharvest (Lopez-Amaya and Marangoni 2000b).

Sphingomyelin (SM) phosphodiesterase (also known as sphingomyelinase or SMase) is a hydrolytic enzyme involved in sphingolipid metabolism and is responsible for the formation of ceramide (and phosphocholine) from sphingomyelin in response to cellular stresses. However, SMase is usually treated separately from "regular" lipases.

Some Applications of Lipases

Dairy Products   Lipases occur naturally in milk and have been shown to be present in the milk of the cow, goat, sheep, sow, donkey, horse, camel, and humans. Perhaps, the natural role of lipases in mammalian milks is to aid digestion for the young suckling. However, in dairy products, lipases play an important role in flavor development: for example, "membrane" lipases can produce undesirable rancidity in freshly drawn milks. In processed milk and milk products, this may not be expected to pose a problem due to the high pH range for milk lipase activity (pH 6–9), the low thermal stability of the lipases, and their inability to survive pasteurization treatments. In some dairy products, post-process lipolysis is desirable to produce the flavors normally associated with such products, such as butterfat, cheddar cheese, blue cheese, and Roquefort cheese. In these products, supplementation with microbial lipases is done to facilitate the ripening process. During "ripening," the added lipases break down milk fat into free fatty acids. Different types of lipases contribute to distinctive flavors. In this regard, lipases that release short-chain fatty acids (i.e., C4–C6) produce "sharp" flavors in food products, while the lipases furnishing long-chain fatty acid (> C12) tend to elicit more subtle tastes (Schmidt and Verger 1998). For example, cheddar cheese has higher levels of butyric acid (C4:0) versus milk fat (Bills and Day 1964). In this regard, lipases from *Penicillium roqueforti*, *A. niger*, *Rhizopus arrhizus,* and *Candida cylindracea* have been found to be very useful (Ha and Lindsay 1993). Although free fatty acids produce distinctive flavors in cheeses and other dairy products, controlling of lipolysis after the desired transformation has been achieved in the product is necessary because excessive lipolysis could induce objectionable rancid flavors in the products (McSweeney and Sousa 2000).

Oleo Products   Oleo products are spreads prepared mostly from vegetable oils and used as a substitute for butter. The term covers a broad spectrum of products ranging from margarines to specialty fats, shortenings, and lard substitutes. The making of oleo products takes advantage of the capacity of lipases to catalyze interesterification reactions that enable modifications in acylglycerols from fats and oils. An example is the making of cocoa butter equivalents. Cocoa butter has 1-palmitoyl-2-oleoyl-3-stearoyl-glycerol (POS) or 1,3-distearoyl-2-oleoyl-glycerol (SOS) as its key components and is widely used in making chocolates and candies. Palm oil mid fraction with its predominant TG as 1,3-dipalmitoyl-2-oleoyl-glycerol has been used as common substrates to mimic cocoa butter by mixing it with co-substrates such as tristearin. In the presence of lipase,

interesterification reactions proceed, whereby fatty acids in *sn*-1 and *sn*-3 positions are interchanged to produce POS and/or SOS. Some commercially available fungal lipases, e.g., lipozyme produced by Novozymes from *Mucor miehei* and Enzymatix F3 produced from *Rhizopus sp.* by Gist-brocades have been shown to be able to carry out such product-simulating interesterification reactions (Bloomer et al. 1983). Immobilized *Rhizopus arrhizus* lipase has been utilized to produce cocoa butter equivalent from oils, and the substrate conversion rate was significantly increased by addition of defatted soy lecithin (Mojović et al. 1993).

Lipase-catalyzed interesterifications are also employed to produce shortenings devoid of *trans*-fatty acids. Shortenings are usually produced by the hydrogenating of vegetable oils and the process forms *trans*-fatty acids as common components. Lipozyme TLIM from *Thermomyces lanuginosus* produces *trans*-fatty acids-free shortening from high oleic acid sunflower oil and fully hydrogenated soybean oil (Li et al. 2010). *Trans*-fatty acids-free shortening was also formed from palm stearin and rice bran oil by using the same lipozyme.

Lipases in Human Health and Disease

In humans, lipase breaks down dietary fats in food so they can be absorbed in the intestines. The enzyme is primarily produced in the pancreas but is also produced in the mouth and stomach. Proper digestion of dietary fat is important prior to their absorption because the end products must be carried in an aqueous milieu (blood and lymph) in which fats are not soluble.

The importance of lipase in the gastrointestinal tract is due to the fact that it is the primary agent for splitting fats into free fatty acids and glycerol. Gastric lipases digest pre-emulsified fats in foods such as egg yolk and cream; however, emulsification in the small intestine followed by lipolysis is the basis for the proper digestion of dietary fats and oils. Emulsification is effected by the action of bile salts produced by the liver and results in the breakdown of the large fat molecules into tiny droplets, which provide lipases with an increased surface area to act on. If bile is insufficient or when the liver is not stimulated to produce bile, fats remain in such large particles that enzymes cannot readily combine with; hence, fat digestion is incomplete and fat absorption is markedly reduced. Most people produce enough pancreatic lipase for this purpose; however, individuals with cystic fibrosis, Crohn's disease, or celiac disease may not have sufficient lipase to assure proper absorption and assimilation of the lipid breakdown products.

Lipases control cell permeability so that nutrients can enter while waste exit. Lipase-deficient individuals have reduced cell permeability; thus, nutrients cannot enter into cells nor can waste metabolites leave. For example, diabetics are lipase-deficient and glucose entry into their cells is impaired, while waste or unwanted substances tend to accumulate in the cells. When lipase is deficient, individuals may suffer health defects including a tendency toward high cholesterol, high TGs, difficulty in losing weight, diabetes or glucosuria, and ultimately cardiovascular diseases.

In humans, inhibition of digestive lipases is important for the control of obesity. The inhibitors act by targeting gastric and

pancreatic lipases. In this regard, an understanding of lipase structure and function relationship as well as lipase catalytic mechanism is crucial for the development of inhibitors for pharmacological and medical use. The well-known drug Orlistat (also known as xenical or tetrahydrolipstatin) used to treat obesity acts by blocking digestive lipase action, leaving consumed fat undigested (Halford 2006). The basic polypeptide, protamine, is a natural lipase inhibitor and acts to hinder fat absorption (Tsujita et al. 1996). Several soy proteins including lipoxygenase-1 are able to inhibit pancreatic and microbial lipases (Satouchi et al. 2002). The inhibitory capacity of soybean proteins has been attributed to interactions with lipids and the ability to transform the substrate emulsion. There are also reports of other promising natural inhibitors of lipases, e.g., medicinal plant extracts (Sharma et al. 2005), polyphenolics, e.g., resveratrol, catechins, and 3-*O-trans-p*-coumaroyl actinidic acid from red wine, green tea, and kiwi fruit (Armand 2007, Koo and Noh 2007, Jang et al. 2008).

While high dietary fat can cause severe adverse health effects (including cardiovascular diseases and cancer), some amount of fat is absolutely required to serve as components of biological membranes, hormones, vitamins, etc. Thus, an adequate supply of essential fats in the diet is important to sustain human health.

Isomerases

This group of enzymes catalyzes structural rearrangement of molecules into their corresponding isomers. Thus, for the general reaction A→B, catalyzed by an isomerase, A and B are isomers. While several isomerases have been characterized in the literature, the one with food use is glucose isomerase, or more specifically, xylose isomerase (Chaplin and Burke 1990). The enzyme is produced from several microorganisms, such as *Actinoplanes missouriensis*, *B. coagulans, Streptomyces albus, S. olivaceus*, and *S. olivochromogenes*, and it normally isomerizes D-xylose to D-xylulose, that is,

D-Xylose ⇔ D-Xylulose

However, this same enzyme can act on D-glucose and isomerize it to D-fructose, that is,

D-Glucose ⇔ D-Fructose

D-fructose is about 30% sweeter than both D-glucose and D-xylose, and plays an important role in the food industry as a sweetener or component of sweeteners; hence, the enzyme is commonly referred to as glucose isomerase instead of its more apt name xylose isomerase.

The free form of the enzyme is quite expensive; thus, it is produced in the immobilized form to permit reuse and reduce cost for the commercial production of fructose from D-glucose. Thus, high-fructose corn syrup (HFCS) is produced through isomerization by glucose isomerase from D-glucose derived from the hydrolysis of corn starch. To make HFCS, corn starch is first converted to liquefied starch by α-amylase and subsequently to glucose by glucoamylase before the isomerization step. The fructose yield in HFCS is temperature dependent, with much higher yields (about 55%) recovered at 95°C versus 42% at the conventional 60–70°C production temperature. The high thermal stability of glucose isomerase permits its use at high temperatures.

ENZYMES IN FOOD AND FEED MANUFACTURE

Enzymes from plants, animals, and microorganisms have been used since time immemorial to modify foodstuffs. Examples of the food enzymes of plant origin include papain, bromelain, and ficin; examples of animal enzymes include rennets, pepsins, trypsins, chymotrypsins, pancreatic lipases, lysozyme, and cathepsins; and examples of microbial enzymes are various amylases, cellulases, proteases, lipases, TGases, glucose isomerase, and GOX derived from selected bacteria, yeasts, and fungi. The uses of these enzymes in foods result in desirable changes with respect to improvements in appearance, consistency, flavor, solubility, texture, and yield, among others. In this regard, enzymes have been used as processing aids in the manufacture of various baked goods, dairy products, meats and fish products, beverages (alcoholic and nonalcoholic), etc. (Table 9.2).

Baked Goods

Baked goods are prepared from flours such as wheat flour, which has starch as its main constituent. Amylolytic enzymes break down flour starch into small dextrins that become better substrates for yeast to act upon in the bread-making process. The use of enzymes in the baking industry is expanding to replace the use of chemicals in making high-quality products, in terms of better dough handling, anti-staling properties, as well as texture, color, taste, and volume. For example, enzymes like GOX and lipase are used in baked goods to strengthen dough texture and enhance elasticity in place of chemicals such as potassium bromate and ascorbate. Other enzymes used in the baking industry include LOX for bleaching flour and strengthening doughs; proteases for degrading and weakening gluten to impart "plastic" properties to doughs and make them more suitable for the making of biscuits; pentosanases (also known as xylanases) for enhancing dough machinability to result in more flexible, easier-to-handle stable doughs that provide better crumb texture and increased loaf volume; and asparaginases employed to curtail the formation of acrylamide in baked goods derived from cereal- and potato-based flours. The enzyme asparaginase breaks down asparagine in the flours to reduce its availability for reaction with reducing sugars to form acrylamide at high temperature.

Dairy Products

The formulation of dairy products entails the use of several enzymes, such as proteases (e.g., microbial rennets or their homologs from calf and other ruminants), lipases, and lactases. The proteases are used to precipitate milk caseins as "clots" or "curds" during cheese-making; the proteases and lipases also promote flavor development during ripening of cheese and in products like coffee whiteners, snack foods, soups, and spreads (margarines); while lactases are used to produce lactose-free

Table 9.2. Selected Food Products and the Enzymes Involved in Their Transformations

Food Products	Group(s) of Enzyme Used in Transformations	Nature of Transformation(s) Induced
Baked goods	• Amylases	• To effect break down of starches to increase reducing sugars to improve fermentation, increase loaf volume, prevent staling, and increase product shelf life
	• Cellulases and xylanases	• To improve conditioning, mixing time, and machinability of doughs
	• Oxidase	• To improve texture/structure of dough, increase dough volume, and reduce the need for emulsifiers and chemical oxidants (e.g. bromates)
	• Proteases	• To break down protein molecules in the dough and improve dough handling; reduce dough mixing time and control dough retraction, enhance flavor development; and to break down gluten and protect individuals that are gluten intolerant
	• Lipase	• To modify fat to reduce dough stickiness, improve stability, and increase volume of doughs; and also enhance flavor
Dairy products	• Proteases	• To act on milk proteins to modify texture and solubility properties of milk and other dairy products; accelerate cheese ripening and improve flavor intensity
	• Lipases	• To transform the fat in milk and other dairy products to produce creamy texture, accelerate ripening, enhance flavor, and increase emulsifying properties
	• Lactase	• To hydrolyze lactose and prevent development of "sandy" taste in frozen ice cream and yoghurts, and protect individuals that are lactose intolerant
	• Transglutaminases (TGases)	• To improve texture and curtail syneresis in yoghurts, and to improve the mouthfeel properties of sugar-free low-calorie food products
	• Catalase	• To break down residual H_2O_2 used for cold pasteurization of milk in certain countries
Starch products	• Amylases, glucoamylases and pullulanases	• To liquefy starch to produce low-viscosity dextrose syrups comprised of maltodextrins and other oligosaccharides; and to saccharify the maltodextrins/oligosaccharides into glucose syrups that are high in reducing sugars (glucose, maltose, and isomaltose)
	• Glucose isomerase (immobilized)	• To isomerize some of the high-glucose syrups (HGS) into fructose—to result in high-fructose syrups (HFS) that are sweeter than glucose and HGS. HFS and HGS are both used as sweeteners in the food and beverage industries
	• Carbohydrases and protease mixtures	• For the break down and removal of starches and proteins from oil seeds during oils extraction, and to facilitate the recovery and improved oil yields
	• Proteases	• To modify grain proteins and improve their utility as animal feed
Alcoholic beverages	• Amylases including glucoamylases (heat-stable forms)	• To liquefy grain starches to increase fermentable sugar (glucose and maltose) content and wort yields, ease clarification and filtration of the beverage, enhance yeast growth and accelerate fermentation rates
	• Cellulases and pectinases	• To break down celluloses and pectic substances in plant materials to facilitate liquefaction, increase fermentable sugar contents, and reduce viscosity for easier handling by yeasts for faster fermentation
	• Proteases	• To break down proteins in plant materials to improve solubility and flavor, facilitate filtration, and prevent post-product haze formation for increased clarity and stability
	• Xylanases and glucanases	• To break down complex carbohydrates (xylans and glucans) to improve filtration and clarity, and reduce residual carbohydrate levels during the manufacture of light beers
	• Mix of glucanases and proteases	• To enhance beer clarity and storage stability, increase solubility and nutritional value, and reduce viscosity haziness in beverages

Table 9.2. (*Continued*)

Food Products	Group(s) of Enzyme Used in Transformations	Nature of Transformation(s) Induced
• Fruit juices (non-alcoholic beverages) • Coffee and tea products	• Pectinases	• To break down and remove pectins to increase yields, facilitate clarification, and improve stability; for peeling operations in some citrus products
	• Mix of cellulases and glucosidases	• To facilitate maceration of high carbohydrate-containing fruits (e.g., mangoes, bananas, and papaya) and vegetables (e.g., carrots and ginger) for better recovery of juices
	• Carbohydrase enzyme mix	• To improve maceration to facilitate and enhance juice extraction, increase juice yields, and enhance color and flavor of juices
	• Naringinase	• To break down naringin and reduce bitterness in citrus juices
	• Glucose oxidase	• For the removal of glucose and head space O_2 from bottled/carton packaged soft drinks and dry mixes
	• Pectinase	• To assist in maceration of tea leaves to improve strength and color
	• Tannases	• To remove tannins
	• Polyphenoloxidases	• To improve enzymatic browning and enhance color of the products
Meats and seafood products	• Proteases (heat stable forms, e.g., papain, ficin, and bromelain)	• To modify texture and induce tenderness in meats and squid, chewability, and digestibility; to reduce bitterness and improve flavor as well as nutritive value, produce hydrolysates from meat scraps, underutilized fish species and fish processing discards; enhanced flavors in fermented herring (matjes)
	• TGases	• To improve texture in meats and seafood products, form restructured meats from trimmings and surimi-type products, some soft-fleshed fish species, form "umami" flavors for use as additives to meat products
	• Mix of proteases and carbohydrases	• To de-skin fish and aid the break down of roe sacs to improve roe yields
Egg products	• Lipases	• To eliminate egg (whole, liquid, or yolk) lipids to preserve its formability
	• Phospholipases	• To modify whole egg or egg yolk to increase its emulsifying and gelling properties
	• Glucose oxidase (GOX)	• To de-sugar powdered eggs and curtail enzymatic browning
	• Catalase	• To break down residual H_2O_2 in egg products or egg ingredients (into H_2O and O_2) after partial sterilization of the eggs with H_2O_2. used to sterilize the product
Dietetic foods	• Pancreatin and glutaminase	• To facilitate digestion and utilization of wheat proteins (gluten) by individuals that are intolerant to gluten
	• Lactase	• To break down milk lactose to enhance safe utilization by lactose intolerants
Protein products	• Proteases	• To hydrolyze proteins derived from yeasts (e.g., single cell proteins), meats, and vegetable such as corn, soy, pulses (e.g., peas and lentils), and wheat to produce highly soluble and low viscosity protein hydrolysates with intense/improved flavors and high nutritive value for use as food ingredients and flavor enhancers; proteases (e.g., chymotrypsins) are also used in food to reduce bitterness due to bitter peptides
	• Carbohydrase mix	• To break down complex carbohydrates in high protein-containing vegetables, and facilitate their removal for the extraction of vegetable proteins in "pure" form and in high yields

(*Continued*)

Table 9.2. (*Continued*)

Food Products	Group(s) of Enzyme Used in Transformations	Nature of Transformation(s) Induced
Candies and confectioneries	• Amylases and invertases	• To produce high-maltose and high-glucose syrups for the manufacture of hard candies, soft drinks, and caramels; and to increase sweetness and aid soft cream candy manufacture; and for the recovery of sugars from candy scraps
	• Amylase, invertase and protease mix	• To improve sweetness, texture, and stability of candied fruits
	• Lipases	• To modify butterfat to increase buttery flavors and reduce sweetness in candies and caramels
Animal feed and pet care	• Cellulases and pectinases	• To facilitate silage production
	• Alkaline proteases	• To decolorize whole blood from abattoirs for use as animal feed
	• Carbohydrase, phytase, and protease mix	• To increase metabolizable energy and protein utilization, reduce viscosity, and liberate bound phosphorous
	• Proteases	• To reduce pain and inflammation and increase wound healing

milk and dairy products for the benefit of individuals that are lactose-intolerant. Catalase from *A. niger* is used to decompose residual H_2O_2 (that is used in some countries as a preservative for milk and whey; Burgess and Shaw 1983) into H_2O and O_2 that are nontoxic unlike H_2O_2.

MEAT AND FISH PRODUCTS

Meat Tenderization

Tenderness in meats relates to the ease of these products to chomping or chewing. Meat tenderness arises from modifications in muscle proteins and entails breakdown of connective tissue proteins by proteases. These hydrolytic enzymes may be naturally present in the post-mortem animal (e.g., cathepsins) or they may be added exogenously. In some meats, the action of the endogenous enzymes may be inadequate to achieve tenderization within a time period that is useful. Exogenous enzymes that are used for household or commercial purposes include thermostable proteases from microbial and plant sources. Some peculiar features of these proteases used as meat tenderizers include their broader specificity and thermostability. Examples are papain, ficin, and bromelain (all from plant sources). The enzymes may be applied by sprinkling over the animal surface or dipping chunks of the meat in a protease solution (mostly in household practices). The disadvantage with these approaches is that the enzymes get unevenly distributed in the meat and results in unequal tenderness in different parts of the meat (e.g., the interior of the meat may invariably be tougher than the outside). Commercial practices include spreading the enzyme throughout the meat either by repeated pre-mortem injections of the protease solutions into the animal prior to slaughter or via post-mortem injections spread over several parts of the carcass.

Fish Processing

Enzymes are used in the fishing industry to achieve a variety of results such as their use in de-skinning fish species that are nor-

mally difficult to de-skin by manual or mechanical operations (e.g., squid, skate, and tuna). De-skinning is achieved using a mixture of proteolytic and glycolytic enzymes (Haard and Simpson 1994, Gildberg et al. 2000, Shahidi and Janak Kamil 2001). Heat-stable fungal and plant proteases are also used to accelerate fish sauce fermentation (Raksakulthai and Haard 1992a,1992b, Haard and Simpson 1994), and proteases are also used to enhance flavor development during the preparation of fermented herring (Matjes; Simpson and Haard 1984) and to tenderize squid meat (Raksakulthai and Haard 1992a,1992b).

ENZYMES IN BEVERAGES

A number of enzymes are used in the manufacture of alcoholic and nonalcoholic beverages. Enzymes such as heat-stable bacterial amylases, glucanases, and pullanases are used to liquefy starches from cereals during mashing to increase fermentable sugar levels in the wort; heat-stable bacterial phytases are used to break down insoluble phytins into phytic acid, which is more soluble and lowers the pH for improved microbial and enzymatic activity in the fermentation medium; and various proteases are used to digest large-molecular weight and water-insoluble proteins (e.g., albumins and globulins) into smaller and soluble peptides in order to curtail haze formation in the products.

The nonalcoholic beverages include juices derived from various fruits (citrus, apples, apricots; and tropical fruits such as avocadoes, bananas, mangoes, and papayas) and vegetables (e.g., carrots), as well as tea, cocoa, and coffee. The enzymes that are used to facilitate the processing of fruits and vegetables into juices include a range of pectinases for peeling the fruits, maceration, removal of pectins, viscosity reduction, and clarification of the juice); amylases and AMGs are applied for breaking down starches in high starch-containing fruits (e.g., unripe apples, bananas) to prevent post-product haze development in the products; cellulases and hemicellulases are used for digesting cellulose and fruit cell wall hemicellulosic materials (i.e., polysaccharides made up of a number of different

monosaccharide units such as xylose, mannose, galactose, rhamnose, and arabinose, and sugar acids such as mannuronic acid and galacturonic acid); and the enzyme naringinase is used for bitterness reduction in citrus fruit juice (e.g., grapefruit juice) processing.

Tea, cocoa, and coffee contain varying levels of caffeine and its related compound theobromine. Thus, intake of beverages derived from these plant materials elicits a stimulant effect in the consumer. Enzymes like polyphenoloxidases and peroxidases promote oxidation and browning reactions during "fermentation" of these products (tea, coffee, and cocoa) as part of the overall darker colors normally associated with these products; in the particular case of coffee, the dark color is enhanced by the roasting of the beans. Amylases are used in cocoa and chocolates to liquefy starches to permit free flow, and in the case of teas, the enzyme tannase breaks down tannins to enhance the solubilization of tea solids. Other enzymes such as invertase, LOX, peroxidases, and proteases also play an important role in flavor development in the beverages derived from these products.

The enzyme GOX is also used to remove head-space O_2 from bottled beverages.

Enzymes in Candies and Confectioneries

Various hydrolytic enzymes are used as processing aids for the manufacture of chocolate-covered soft cream candies, e.g., amylases and invertase, and for the recovery of sugars from candy scraps, e.g., amylases, invertase, and proteases (Cowan 1983). A mixture of cellulases, invertase, pectinases, and proteases are used in making candied fruits (Mochizuki et al. 1971). Amylases are also used to produce high-maltose and high-glucose syrups for use as sweetener in the manufacture of hard candies, soft drinks, and caramels. Lipases are used to modify butterfat to increase buttery flavors in candies and caramels and to reduce sweetness as well (Burgess and Shaw 1983).

Enzymes in Animal Feed and Pet Care

Agricultural (used here to encompass plant, livestock, and fish) harvesting and processing discards are high in useful nutrients such as carbohydrates (both starch and nonstarch types), proteins, and lipids, some of which cannot be fully digested and utilized directly by animals. In general, the discards are used as feed for animals. Different kinds of enzymes are added to these source materials to modify them into forms that are more amenable to digestion and utilization for improved feed efficiency. Examples of enzymes used for this purpose include microbial amylases, cellulases, glucanases, xylanases, phytases, and proteases, to degrade simple and complex carbohydrates, as well as proteins. Cellulases and pectinases also play an important role in silage production, while alkaline proteases (from bacteria and fungi) are employed for enzymatic decolorization of whole blood from abattoirs for use as animal feed protein. The enzymatic action results in an increase in available metabolizable energy and protein utilization, reduced viscosity, and liberation of bound phosphorous.

Enzymes are also used in pet care to provide relief from the effects of dry or scaly hair coats, skin problems, digestive and immune disorders, weight problems, allergies, bloating, and other disorders that afflict household pets. Enzymes are also used to enhance wound healing and rectify soreness, pain, and inflammations suffered by highly active as well as arthritic pets.

A summary of various foods produced commercially (and/or in households) via enzyme-assisted transformations is provided in Table 9.2.

CONTROLLING ENZYMATIC ACTIVITY IN FOODS

The action of enzymes in foods may not always be desirable. For example, continued enzymatic activity in foods after they have been used to attain the desired transformation could adversely affect food quality. The natural presence of certain enzymes in agricultural materials (e.g., LOX, PPO, peroxidases, and lipases) may induce undesirable changes (e.g., color loss, dark discolorations, and rancidity) in foods; the action of some naturally occurring enzymes (e.g., histidine decarboxylases) may produce toxic compounds (biogenic amines) in food products; and yet other enzymes (e.g., thiaminase and ascorbic acid oxidase) may act to destroy essential food components (e.g., vitamins B_1 and C). Thus, it is necessary to control enzymatic activity in food stuffs to obviate the potential deleterious effects they cause in these products. There are several factors that are known to affect enzyme activity and influence their behavior in foods. The factors include temperature, pH, water activity (A_w), and chemicals (inhibitors, chelating agents, and reducing agents), and advantage is taken of this fact by food technologists and food manufacturers to develop or rationalize procedures to control enzymatic activity in foods.

Temperature Effects

Temperature can affect the activity and stability of enzymes (as well as the substrate the enzymes act on). Thus, temperature effects on enzyme activity are mixed. Temperatures modulate the motion of biomolecules (both enzymes and their substrates) as well as interactions between molecules.

Heat Treatments

An increase in temperature (up to the temperature optimum of the enzyme) generally elevates the average kinetic energy of enzyme molecules and their substrates, and manifests as increased rates of enzyme catalyses. However, beyond the optimum temperature, further increases in temperature do not increase the average kinetic energy of molecules, rather they disrupt the forces that maintain the conformation and structural integrity of the molecules that are crucial for their stability and normal catalytic activity. Under those circumstances, enzyme molecules undergo denaturation, inactivation, and lose catalytic activity. The heat denaturation may be reversible or irreversible depending on the severity and/or duration of the heat treatment. Advantage is taken of this heat inactivation of enzymes in processes such as

sterilization, blanching, UHT, high temperature short term treatment, pasteurization, and related thermal treatments to curtail undesirable enzymatic reactions in food and protect foods from enzyme-induced postharvest and post-processing spoilage that could arise from enzymes naturally occurring in food materials, or from enzymes deliberately added to foods to bring about particular transformations. Nevertheless, thermal processing of foods has the disadvantage of destroying heat-labile essential components in foods such as some vitamins and essential oils, thus the need for effective nonthermal techniques.

Low Temperature Treatments

A decrease in temperature slows down the average kinetic energy of biomolecules such as enzymes and their substrates. The molecules are sluggish at low temperatures and collide less frequently and effectively with one another, thus reaction rates are relatively slow. Hitherto, advantage is taken of lower thermal energy in approaches such as refrigeration, iced storage, refrigerated sea water storage, and frozen storage to slow down the undesirable effects of enzymes in foods after harvest. Low temperature treatments are generally used to slow down the deleterious effects of enzymes in fresh foods (vegetables, eggs, seafood, and meats); however, other processed food products such as high-fat food spreads (margarine and butter), vacuum-packaged meats and seafood products, pasteurized milk, cheeses, and yoghurt also benefit from the desirable effects derived from low temperature treatments.

It must be noted here that there are some enzymes that are quite stable and active in extreme temperatures (high- or low-temperature-adapted enzymes—known as extremophiles), which may survive the traditional temperature treatments and induce autolysis and spoilage in foods. For these enzymes, other techniques are needed to stop their undesirable effects.

Low-temperature treatments (refrigeration, chilling, and freezing) all slow down enzyme activity but do not completely inactivate the enzymes. Enzymatic activity still takes place in foods thus treated, albeit at much reduced rates. Once the food material is out of the source of the low temperature, once the frozen food material is thawed, enzyme activity may restart and cause undesirable autolytic changes in foods. Refrigerated and chilled storage in particular may not be considered as effective methods for long-term storage of fresh foods in high quality.

Effect of pH

Enzyme activity in foods is pH dependent (Table 9.3). In general, enzymes tend to be destabilized and irreversibly inactivated at extreme pH values, and advantage is taken of this property of pH to control enzymatic activity in foods. For example, the enzyme PPO is known to cause undesirable browning in fresh fruits and vegetables. By adding acids such as citrate, lactate, or ascorbate, acidic conditions are created (around pH 4) where the PPO enzyme is inactive. A similar effect is achieved when glucose/catalase/GOX cocktail is used on raw crustacea (e.g., shrimp); the GOX oxidizes the glucose to gluconic acid and this is accompanied by a drop in pH, which inactivates the PPO.

Table 9.3. pH Stabilities of Selected Enzymes

Enzyme	pH Stability Optimum
Pepsin	1.5
Malt amylase	4.5–5.0
Invertase	4.5
Gastric lipase	4.0–5.0
Pancreatic lipase	8.0
Maltase	6.5
Catalase	7.0
Trypsin	8.0

In household food preparations, vinegar or lemon juice is often sprinkled on fresh foods (e.g., vegetable salads) to prevent dark discolorations. Lowering pH of citrus juice with HCl has been used to achieve irreversible inactivation of pectin esterase (PE; Owusu-Yaw et al. 1988), and LOX activity in soy flour is drastically reduced at pH $\leq$ 5.0 (Thakur and Nelson 1997).

Effect of Inhibitors

Enzyme inhibitors are substances that slow down or prevent catalytic activities of enzymes. They do this by either binding directly to the enzyme or by removing co-substrates (e.g., O_2 in enzymatic browning) in the reaction catalyzed by particular enzymes. Enzyme inhibitors fall into several categories, such as reducing agents that remove co-substrates such as O_2 (e.g., sulfites and cysteine), metal chelators that bind or remove essential metal cofactors from enzymes (e.g., EDTA, polycarboxylic acids, and phosphates), acidulants that reduce pH and cause enzyme inactivation (e.g., phosphoric acids, citric acid, sorbates, benzoates), and enzyme inhibitors that bind directly to the enzymes and prevent their activity (e.g., polypeptides, organic acids, and resorcinols). Food-grade protein inhibitors from eggs, bovine/porcine plasma, and potato flour are all used to control undesirable proteolytic activity in foods. Egg white contains ovomucoid, a serine protease inhibitor; bovine and porcine plasmas have the broad spectrum protease inhibitor α_2-macroglobulin; and potato flour has a serine protease inhibitor (potato serine protease inhibitor or PSPI). Fractions containing these inhibitors have been used to prevent surimi texture softening due to proteolysis (Weerasinghe et al. 1996).

Effect of Water Activity

Enzymatic activity depends to the availability of water. Water availability, and hence water activity (A_w), in foods may be modified by using procedures that remove moisture, such as drying, freezing, addition of water-binding agents or humectants (such as salt, sugar, honey, glycerol, and other polyols), and by lyophilization (Tejada et al. 2008). Most enzyme-catalyzed reactions require moisture to progress effectively for several reasons: (i) a thin film of moisture (bound water) is required to maintain proper enzyme conformational integrity for functional activity, (ii) to solubilize substrates and also serve as the reaction medium,

and (iii) to participate in the reaction as co-reactant. When moisture content is reduced by dehydration, there is conformational destabilization and loss of catalytic activity. For example, most enzymes such as proteases, carbohydrases, PPO, GOX, and peroxidases require $A_w \geq 0.85$ to have functional activity, the well-known exceptions being lipases that may actually gain in activity and remain active at A_w of 0.3, perhaps as low as 0.1 (Loncin et al. 1968). The unusual behavior of lipases is observed in lipase-catalyzed reactions with their water-insoluble substrates, lipids, and is due to the interfacial phenomenon that proceeds better in a reduced moisture milieu. Foodstuffs prepared based on A_w reduction to control the undesirable effects of enzymes (and microorganisms) include the use of sugar in food spreads (jams and jellies), salt in pickled vegetables, glycerol in cookies and liqueurs, and gelatin in candies and confectioneries.

EFFECT OF IRRADIATION

Irradiation of foods (also known as cold pasteurization) is a process during which foods are subjected to ionizing radiations to preserve them. Food irradiation methods entail the use of gamma rays, X-rays, and accelerated electron beams, and can preserve food by curtailing enzymatic (and microbial) activities. However, the irradiation dosage needed to achieve complete and irreversible inactivation of enzymes may be too high and could elicit undesirable effects of their own (e.g., nutrient loss) in food materials. The technique is used to some extent in meats, seafood, fruits, and vegetables (especially, cereal grains) for long-term preservation; however, the procedure has low appeal and acceptability to consumers and, therefore, not extensively used in food processing.

EFFECTS OF PRESSURE

High-pressure treatment, also known as high-pressure processing (HPP) or ultra high-pressure processing, is a nonthermal procedure based on the use of elevated pressures (400–700 MPa) for processing foods. At the elevated pressures, there is inactivation of both enzymes and microorganisms, the two foremost causative agents of food spoilage, and the inactivation arises from conformational changes in the 3D structure of the enzyme protein molecules (Cheftel 1992). Enzymes in foodstuffs display different sensitivities to pressure; while some may be inactivated at relatively low pressures (few hundred MPa), others can tolerate pressures up to a thousand MPa. The pressure effects may also be reversible in some enzymes and irreversible in others, depending on the pressure intensity and the duration of the treatment. Those enzymes that can tolerate extreme pressures may be deactivated using appropriate pressure treatments in combination with other barriers to enzyme activity such as such as temperature, pH, and/or inhibitors (Ashie and Simpson 1995, Ashie et al. 1996, Sareevoravitkul et al. 1996, Katsaros et al. 2010).

HPP has minimal effects on the attributes of food, such as flavor, appearance, and nutritive value, compared with other procedures like thermal processing, dehydration, or irradiation. In contrast to those other processing methods, high-pressure treat-

ments keep foods fresher and highly nutritious, improve food texture, make foods look better and taste better. The HPP approach also retains the native flavors associated with foods, protects heat-labile essential food components, and extends product shelf life with minimum need for chemical preservatives. The technology has been used mostly by companies in Japan and the United States to process foods such as ready-to-eat meats and meat products, food spreads (jams), fresh juices and beverages (sake), processed fruits and vegetables, fresh salads, and dips. HPP is also used to shuck and retrieve meats from shellfish (oysters, clams, and lobster).

CONCLUDING REMARKS: FUTURE PROSPECTS

Foodstuffs have naturally present enzymes as well as intentionally added ones that produce significant effects on food-processing operations. The actions of these enzymes may improve food quality or promote food quality deterioration. The use of enzymes as food-processing aids has increased steadily for several years now, and this trend is expected to continue for the foreseeable future due to the interest and need for more effective strategies and greener technologies to curtail the reliance on existing technologies and protect the environment. The factors that augur well for the expanded use of enzymes as food-processing aids include: consumer preferences for their use instead of chemicals, their use as food-processing aids is perceived to be more innocuous and more environmental friendly, their capacity to selectively and specifically remove toxic components in foods (e.g., glucosinolates with sulfatases, acrylamide with asparaginase, or phytates with phytases), and recent advances in enzyme engineering, which is permitting the discovery and design of new and superior enzymes tailored to suit specific applications.

Recent developments in enzyme engineering are enabling yields of particular enzymes to be improved by increasing the number of gene copies that code for enzyme proteins in safe host organisms, and this feature is particularly significant because they are permitting useful enzymes from plant and animal sources, and even their counterparts from uncertified microorganisms (including hazardous ones) to be produced in high yields much more consistently, rapidly, and safely for food use. It is also significant because the cultivation and growth of microorganisms for the purpose of producing recombinant enzymes is not dependent of weather conditions, proceeds much faster, and require much lesser space and regulations compared with plants or animals.

Enzyme engineering is also facilitating the design of new enzyme structures with superior performance characteristics with respect to catalytic activity, thermal stability, tolerance to pH and inhibitors, and other properties to make them more suited for applications in several fields of endeavor. This capacity is also expected to enhance the design and creation of synthetic or artificial enzymes (Chaplin and Burke 1990) with superior properties for both food and nonfood uses. Recombinant enzymes with improved stability would facilitate their use in producing

more useful biosensors for food analysis and other analytical work (Chaplin and Burke 1990), stimulate the manufacture of more immobilized enzymes that are also endowed with superior properties for reuse and cost savings in food processing, produce new enzymes that can function well in nonaqueous milieu, and facilitate the synthesis of new molecules with predetermined structures and functions (as was achieved with the synthesis of aspartame by thermolysin) for use in foods. Recombinant enzyme technology is also expected to facilitate the discovery of newer applications for enzymes as food-processing aids and also produce new enzymes to assist the incorporation of specific essential molecules in food products to meet specific dietary needs, as use as dietary supplements to manipulate ingested carbohydrates, lipids, and cereal proteins (e.g., gluten) for improved human health and wellness.

The undesirable effects of enzymes in foods are controlled to some extent by traditional practices such as thermal treatments, cold storage, water activity (A_w) reduction, pH control, and treatment with chemicals. However, there are various limitations with these methods, such as destruction of heat-labile essential components in foods, continued enzymatic activity (albeit at a reduced rate) even under iced, refrigerated, or frozen storage; and the adverse effects of A_w reducing agents such as salt or sugar as well as chemicals on human health. Novel approaches based on nonthermal treatments for controlling enzymes (such as HPP and PEF) are promising, and studies to optimize their use either exclusively or in combination with each other or other barriers would be useful. Enzyme engineering provides a unique opportunity for exploiting the distinct capacity of enzymes from animals with no anatomical stomachs to inactivate native protein (and enzymes) molecules (Pfleiderer et al. 1967, Simpson and Haard 1987, Guizani et al. 1992, Brown 1995) in food processing. Thus, new enzymes designed to specifically recognize and bind undesirable native enzyme molecules (e.g., PME in fruit juices) could have a major impact on the use of nonthermal strategies to control the deleterious effects elicited by certain food enzymes.

Protein Cross-linking in Food – Structure, Applications, Implications for Health and Food Safety

Juliet A. Gerrard and Justine R. Cottam

Abstract: The capacity of proteins to cross-link with each other has important implications for food quality. Protein cross-linking can influence food texture and appearance, or permit the incorporation of useful nutrients such as essential amino acids or essential oils in foods to accrue crucial benefits. Protein cross-linking in foods may be achieved by enzymatic means with transglutaminase or with cross-linking agents like glutaraldehyde. This chapter discusses the different cross-linking effects and how they may be exploited by food processor.

INTRODUCTION

Protein cross-links play an important role in determining the functional properties of food proteins. Manipulation of the number and nature of protein cross-links during food processing offers a means by which the food industry can manipulate the functional properties of food, often without damaging the nutritional quality. This chapter updates the chapter in the previous edition of this book and discusses advances in our understanding of protein cross-linking over the last two decades, as well as examining current and future applications of this chemistry in food processing and its implications for health and food safety. It draws on, and updates, two reviews in this area (Gerrard 2002, Miller and Gerrard, 2005) in addition to earlier reviews on this subject (Matheis and Whitaker 1987, Feeney and Whitaker 1988, Singh 1991).

The elusive relationship between the structure and the function of proteins presents a particular challenge for the food technologist. Food proteins are often denatured during processing, so there is a need to understand the protein both as a biological entity with a predetermined function and as a randomly coiled biopolymer. To understand and manipulate food proteins requires a knowledge of both protein biochemistry and polymer science. If the protein undergoes chemical reaction during processing, both the 'natural' function of the molecule and the properties of the denatured polymeric state may be influenced. One type of chemical reaction that has major consequences for protein function in either their native or denatured states is protein cross-linking. It is, therefore, no surprise that protein cross-linking can have profound effects on the functional properties of food proteins.

This chapter sets out to define the different types of protein cross-links that can occur in food, before and after processing, and the consequences of these cross-links for the functional and nutritional properties of the foodstuff. Methods that have been employed to introduce cross-links into food deliberately are then reviewed, and future prospects for the use of this chemistry for the manipulation of food during processing are surveyed, including a consideration of health and food safety aspects.

PROTEIN CROSS-LINKS IN FOOD

Protein cross-linking refers to the formation of covalent bonds between polypeptide chains within a protein (intramolecular cross-links) or between proteins (intermolecular cross-links) (Feeney and Whitaker 1988). In biology, cross-links are vital for maintaining the correct conformation of certain proteins and may control the degree of flexibility of the polypeptide chains. As biological tissues age, further protein cross-links may form, which often have deleterious consequences throughout the body and play an important role in the many conditions of ageing (Zarina et al. 2000, Ahmed 2005, Nass et al. 2007, GuI et al. 2009). Chemistry similar to that which occurs during ageing may take place if biological tissues are removed from their natural environment – for example, when harvested as food for processing.

Food processing often involves high temperatures, extremes in pH, particularly alkaline, and exposure to oxidising conditions and uncontrolled enzyme chemistry. Such conditions can result in the introduction of protein cross-links, producing substantial changes in the structure of proteins, and therefore the functional (Singh 1991) and nutritional (Friedman 1999a, 1999b, 1999c) properties of the final product. A summary of protein cross-linking in foods is given in Figure 10.1, in which the information is organised according to the amino acids that react to form the cross-link. Not all amino acids participate in protein cross-linking, no matter how extreme the processing regime. Those that react do so with differing degrees of reactivity under various conditions.

Disulfide Cross-links

Disulfide bonds are the most common and well-characterised types of covalent cross-link in proteins in biology. They are formed by the oxidative coupling of two cysteine residues that are close in space within a protein. A suitable oxidant accepts the hydrogen atoms from the thiol groups of the cysteine residues, producing disulfide cross-links. The ability of proteins to form intermolecular disulfide bonds during heat treatment is considered to be vital for the gelling of some food proteins, including milk proteins, surimi, soybeans, eggs, meat and some vegetable proteins (Zayas 1997). Gels are formed through the cross-linking of protein molecules, generating a three-dimensional solid-like network, which provides food with desirable texture (Dickinson 1997).

Disulfide bonds are thought to confer an element of thermal stability to proteins and are invoked, for example, to explain the stability of hen egg white lysozyme, which has four intramolecular disulfide cross-links in its native conformation (Masaki et al. 2001). This heat stability influences many of the properties of egg white observed during cooking. Similarly, the heat treatment of milk promotes the controlled interaction of denatured β-lactoglobulin with κ-casein through the formation of a disulfide bond. This increases the heat stability of milk and milk products, preventing precipitation of β-lactoglobulin (Singh 1991). Disulfide bonds are also important in the formation of dough. Disulfide interchange reactions during the mixing of flour and water result in the production of a protein network with the viscoelastic properties required for bread making (Lindsay and Skerritt 1999). The textural changes that occur in meat during cooking have also been attributed to the formation of intermolecular disulfide bonds (Singh 1991).

Cross-links Derived from Dehydroprotein

Alkali treatment is used in food processing for a number of reasons, such as the removal of toxic constituents and the solubilisation of proteins for the preparation of texturised products. However, alkali treatment can also cause reactions that are undesirable in foods, and its safety has come into question (Savoie et al. 1991, Shih 1992, Friedman 1999a, 1999c). Exposure to alkaline conditions, particularly when coupled to thermal processing, induces racemisation of amino acid residues and the formation of covalent cross-links, such as dehydroalanine, lysinoalanine and lanthionine (Friedman 1999a, 1999b, 1999c). Dehydroalanine is formed from the base-catalysed elimination of persulfide from an existing disulfide cross-link. The formation of lysinoalanine and lanthionone cross-links occurs through β-elimination of cysteine and phosphoserine protein residues, thereby yielding dehydroprotein residues. Dehydroprotein is very reactive with various nucleophilic groups, including the ε-amino group of lysine residues and the sulfhydryl group of cysteine. In severely heat- or alkali-treated proteins, imidazole, indole and guanidino groups of other amino acid residues may also react (Singh 1991). The resulting intra- and intermolecular cross-links are stable, and food proteins that have been extensively treated with alkali are not readily digested, reducing their nutritional value. Mutagenic products may also be formed (Friedman 1999a, 1999c).

Cross-links Derived from Tyrosine

Various cross-links formed between two or three tyrosine residues have been found in native proteins and glycoproteins, for example in plant cell walls (Singh 1991). Dityrosine cross-links have recently been identified in wheat and are proposed to play a role in the formation of the cross-linked protein network in gluten (Tilley et al. 2001). They have also been formed indirectly by treating proteins with hydrogen peroxide or peroxidase (Singh 1991) and are implicated in the formation of caseinate films by gamma irradiation (Mezgheni et al. 1998). Polyphenol oxidase can also lead indirectly to protein cross-linking, due to reaction of cysteine, tyrosine, or lysine with reactive benzoquinone intermediates generated from the oxidation of phenolic substrates (Matheis and Whitaker 1987, Feeney and Whitaker 1988). Such plant phenolics have been used to prepare cross-linked gelatin gels to develop novel food ingredients (Strauss and Gibson 2004).

Cross-links Derived from the Maillard Reaction

The Maillard reaction is a complex cascade of chemical reactions, initiated by the deceptively simple condensation of an amine with a carbonyl group, often within a reducing sugar or fat
Figure 10.1. A summary of the cross-linking reactions that can occur during food processing, from Gerrard 2002. Further details are given in the text.

breakdown product (Fayle and Gerrard 2002, Friedman 1996a). During the course of the Maillard reaction, reactive intermediates, such as α-dicarbonyl compounds and deoxysones, are generated and lead to the production of a wide range of compounds, including polymerised brown pigments called melanoidins, furan derivatives, nitrogenous, and heterocyclic compounds (e.g. pyrazines; Fayle and Gerrard 2002). Protein cross-links form a subset of the many reaction products, and the cross-linking of food proteins by the Maillard reaction during food processing

is well established (Gerrard 2002, Miller and Gerrard, in press, 2006). The precise chemical structures of these cross-links in food, however, are less well understood. Thus, surprisingly little is known about the extent of Maillard cross-linking in processed foods, the impact of this process on food quality, and how the reaction might be controlled to maximise food quality.

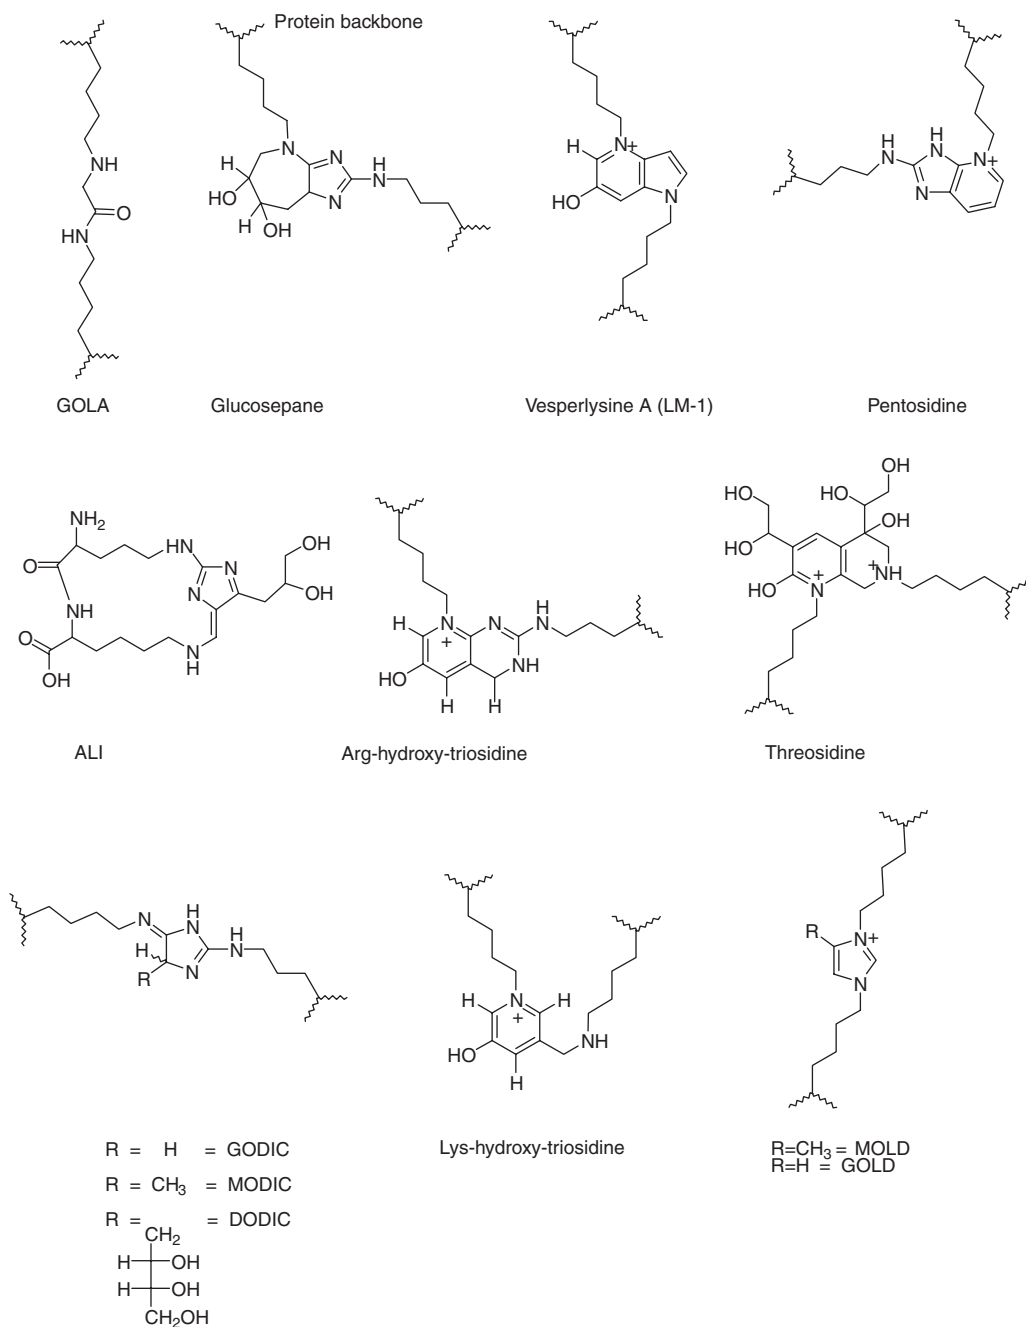
In biology and medicine, where the Maillard reaction is important during the ageing process, several cross-link structures have


Figure 10.2. A selection of known protein cross-links derived from the Maillard reaction in the body, from Miller and Gerrard (2004). (Sell and Monnier 1989, Nakamura et al. 1997, Prabhakaram et al. 1997, Brinkmann-Frye et al. 1998, Lederer and Buhler 1999, Lederer and Klaiber 1999, Al-Abed and Bucala 2000, Glomb and Pfahler 2001, Biemel et al. 2002 Tessier et al. 2003). The extent to which these cross-links are present in food is largely undetermined. GOLA, N^6-{2-[(5-amino-5-carboxypentyl)amino]-2-oxoethyl}lysine; ALI, arginine–lysine imidazole; GODIC, N^6-(2-{[(4S)-4-ammonio-5-oxido-5-oxopentyl]amino}-3,5-dihydro-4H-imidazol-4-ylidene)-L-lysinate; MODIC, N^6-(2-{[(4S)-4-ammonio-5-oxido-5-oxopentyl]amino}-5-methyl-3,5-dihydro-4H-imidazol-4-ylidene)-L-lysinate; DOGDIC, N^6-{2-{[(4S)-4-ammonio-5-oxido-5-oxopentyl]amino}-5[(2S,3R)-2,3,4-trihydroxybutyl]-3,5-dihydro-4H-imidazol-4-ylidene)-L-lysinate; MOLD, methylglyoxal lysine dimer; GOLD, glyoxal lysine dimer.

been identified, including those shown in Figure 10.2 (Ames 1992, Hill et al. 1993, Easa et al. 1996a, 1996b, Gerrard et al. 1998a, 1999, 2002a, 2003a, 2003b, Hill and Easa 1998, Fayle et al. 2000, 2001, Mohammed et al. 2000). One of the first protein-derived Maillard reaction products (MRPs) isolated and characterised was the cross-link pentosidine (Sell and Monnier 1989, Dyer et al. 1991), a fluorescent moiety that is believed to form through the condensation of a lysine residue with an arginine residue and a reducing sugar. The exact mechanism of formation of pentosidine remains the subject of considerable debate (Chellan and Nagaraj 2001, Biemel et al. 2001).

Some of the earliest studies that assessed the effect of protein cross-linking on food quality examined the digestibility of a model protein following glycation. Kato et al. (1986a) observed that following incubation of lysozyme with a selection of dicarbonyl compounds for 10 days, the digestibility of lysozyme by a pepsin-pancreatin solution was reduced to up to 30% relative to the non-glycated sample. This trend of decreasing digestibility was concomitant with an observed increase in cross-linking of lysozyme. The increased resistance of cross-linked proteins to enzymes commonly involved in the digestion of proteins in the body is unfavourable from a nutritional standpoint. It has also been reported that the digestion process can be inhibited by the Maillard reaction (Friedman 1996b).

AGE PROTEIN CROSS-LINKS ISOLATED TO DATE IN FOOD

Information regarding the presence of specific Maillard protein cross-links in food is, to date, limited, with only a handful of studies in this area (Henle et al. 1997, Schwarzenbolz et al. 2000, Biemel et al. 2001). For example, compared with the extensive literature on the Maillard chemistry in vivo, relatively little has been reported on the existence of pentosidine in food. In a study by Henle et al. (1997), the pentosidine content of a range of foods was examined, with the highest values observed in roasted coffee. Overall concentrations, however, were considered low, amongst most of the commercial food products tested. It was, therefore, concluded that pentosidine does not have a major role in the polymerisation of food proteins. Schwarzenbolz et al. (2000) showed that pentosidine formation in a casein-ribose reaction is carried out under high hydrostatic pressure, which could be relevant to some areas of food processing. Iqbal et al. have investigated the role of pentosidine in meat tenderness in broiler hens (Iqbal et al. 1997, Iqbal et al. 1999a, 1999b, Iqbal et al. 2000).

Other Maillard cross-links have recently been detected in food, and attempts have been made to quantify the levels found. Biemel et al. (2001) examined the content of the lysine–arginine cross-links, GODIC, MODIC, DODIC and glucosepane in food. These cross-links were found to be present in proteins extracted from biscuits, pretzels, salt stick and egg white in the range of 7–151 mg/kg. The lysine–lysine imidazolium cross-links MOLD and GOLD were also isolated but were present at a lower concentration than MODIC and GODIC.

HEALTH AND FOOD SAFETY ASPECTS OF MRPS

The complexity of the Maillard reaction means that during any cross-linking reaction in the food matrix, a variety of other products are likely to form. Over the last decade, there has been an ongoing debate over the health and safety impacts of dietary MRPs, particularly advanced glycation end products (AGEs) generated in the later stages of the Maillard reaction in foods, with regards to their potential risks and/or benefits towards human health when consumed in the diet. To date, numerous research groups have argued that MRPs pose a risk to human health, particularly certain heterocyclic products, when consumed in the diet (Felton and Knize 1998, Faist and Erbersdobler 2002, Shin 2003, Shin et al. 2003, Bordas et al. 2004, Murkovic 2004, Taylor et al. 2004, Sebekova and Somoza 2007, Garcia et al. 2009). Other research has provided evidence to the contrary, highlighting the potential of MRPs to act as antioxidants or have other beneficial effects (Manzocco et al. 2000, Faist and Erbersdobler 2002, Lee and Shibamoto 2002, Morales and Babbel 2002, Dittrich et al. 2003, Morales and Jimenez-Perez 2004, Ames 2007), with a few groups considering both the positive and negative effects of MRPs when consumed in the diet (Faist and Erbersdobler 2002, Somaza 2005, Gerrard 2006, Henle 2007).

This ongoing debate was discussed by Henle (2007) in a review paper, in which he explored whether dietary MRPs are a risk to human health based on the arguments from two prominent papers on the topic by Ames (2007), who provided evidence against the MRPs being a risk to human health, and Sebekova and Somoza (2007), who argued the opposite. Both sides of the debate are outlined here.

Sebekova and Somoza (2007) argued that there was sufficient evidence concerning the negative impact of dietary AGEs on health. Their argument is based on research from both experimental studies in rodents and clinical studies in humans, including healthy people and those suffering from diseases that are associated with AGEs, such as diabetes and cardiovascular disease. Their analysis of the current literature revealed that a high intake of thermally processed foods in the diet may have significant nephrotoxic effects, aggravate low levels of inflammation and exert oxidative stress. There is also significant evidence to show that a high AGE-diet can influence the development of complications that are associated with diabetes and have detrimental effects on, for example, wound healing (Peppa et al. 2003, 2009) and atherosclerois (Lin et al. 2003, Walcher and Marx 2009). This is supported by further studies that show potential negative effects of an AGE-rich diet to health. The first of these studies was an animal study in which Wistar rats were fed either an AGE-rich diet or an AGE-poor diet over a 6-week period, where wheat starch was replaced by bread crusts (Sebekova et al. 2005, Somoza et al. 2005). The results obtained were interesting, with the rats on the AGE-rich diet gaining weight more rapidly than those on the AGE-poor diet, with a trend towards higher glucose and albumin levels. There was also noticeable weight gain in specific organs such as the heart, kidney, liver and lungs, but not the spleen, intestine or brain. These results suggest the idea that some organs are more susceptible to

MRP-rich diets. Similar results were found in a crossover study carried out by Wittmann et al. (2001) on 21 healthy volunteers, where those on the AGE-rich diet gained more weight. In this study, 21 healthy volunteers were fed on either an AGE-rich or AGE-poor diet of heated or unheated high protein (3 g/kg/day). However, to date, the majority of knowledge on the effects of AGE-rich diets is mainly based on experimental studies of rodents rather than human studies.

In contrast, Ames (2007) supports the idea that dietary AGEs are not a risk to human health and provides evidence to support this claim based on information obtained from both animal and human volunteer studies on the bioavailability and metabolic fate of dietary AGEs. The majority of the literature to date on the bioavailability and metabolic fate of AGEs is centred on the compounds CML and pyrraline, due to their abundance in food systems. Various studies have investigated the metabolic fate of dietary CML. One such study involved feeding rats on a diet of glycated casein (either 1.8 g of CML/kg or 6.2 g of CML/kg) against the control of native casein (Faist et al. 2000). The results found that approximately 50% of the initial CML consumed was excreted through urine and faeces, with a small portion being deposited on the kidney and liver. Although the majority of the CML consumed was readily excreted, further investigations would need to be carried out to determine the metabolic fate of the rest of the CML, with suggestions that it could have been degraded by the colonic microflora or metabolised post-absorption. Another study looked at distribution and elimination of AGEs, including CML, CEL (N^e-carboxyethyllysine) and lysine (Bergmann et al. 2001). These AGEs were studied via fluorine-18-labelled analogues by [18F]-fluorobenzoylation of the α-amino group of the AGE and then intravenously injected into the tail vein of rats, which were subsequently sacrificed within 30 minutes of the injection. The results obtained showed all three compounds (CML, CEL and lysine) to be distributed swiftly through the body and be rapidly excreted via the kidneys with >87% of the radioactivity being excreted within 2 hours of injection (Bergmann et al. 2001).

Many studies have been carried out investigating the distribution and elimination of the other abundant AGE, pyrraline, which is excreted via the kidneys within 48 hours (Förster and Henle 2003). Other studies on excretion of pentosidine, another MRP, in the body, as well pyrraline and fructoselysine (Miyata et al. 1998, Förster et al. 2005) have found significant differences in the excretion rate of the individual MRPs, according to individual metabolic fates and whether the MRPs are free or protein bound. However, the weight of evidence appears to suggest that the majority of the ARPs and AGEs that are absorbed by the body are subsequently, rapidly excreted and are therefore considered not to be harmful to the body. Seiquer et al. (2008) carried out experiments on healthy adolescent males by feeding some of the participants a MRP-rich diet and the others a low MRP diet over a two-week period. Surprisingly, they found there was no obvious damage to the oxidative status or antioxidant defence in the MRP-rich diet participants. Lindenmeier et al. (2002) and Somoza et al. (2005) have suggested beneficial effects of AGEs. Definitive conclusions await detailed research on the bioactivity of dietary AGEs (Lopez-Garcia et al. 2004).

Ames (2009) suggests there needs to be a more holistic approach to the research of MRPs. The balance of evidence, based on many centuries of eating cooked food, is that MRPs/AGEs are not harmful, but further studies should be done to eliminate the possibility and provide reassurance to food manufacturers and consumers. An interdisciplinary approach incorporating food science, biology, chemistry and medicine is required for a better understanding into the biological consequences of thermally processed foods and more carefully defined human trials should resolve this. Food manufacturers wishing to harness the Maillard reaction for protein cross-linking or other uses are advised to keep a watching brief on this research.

MELANOIDINS

Very advanced glycation end-products that form as a result of food processing are dubbed melanoidins. This is a structurally diverse class of compounds, which until recently were very poorly characterised. However, a subset of food melanoidins undoubtedly includes those that cross-link proteins.

Melanoidins can have molecular weights of up to 100,000 Da (Hofmann 1998a). Because of their sheer chemical complexity, it has been difficult to isolate and characterise these molecules (Fayle and Gerrard 2002, Miller and Gerrard, 2005). However, some recent work in this area has lead to some new hypotheses. Hofmann proposed that proteins may play an important role in the formation of these complex, high-molecular weight melanoidins (Hofmann 1998b). Thus, it was proposed that a low-molecular weight carbohydrate-derived colourant reacts with protein-bound lysine and/or arginine, forming a protein cross-link. Formation of colour following polymerisation of protein has indeed been observed following incubation with carbohydrates (Cho et al. 1984, 1986a, 1986b, Okitani et al. 1984). Hofmann tested this hypothesis by the reaction of casein with a pentose-derived intermediate furan-2-carboxaldehyde and subsequent isolation of a melanoidin-type colourant compound from this reaction mixture (Figure 10.3). Although non-cross-linking in nature, the results encouraged further studies to isolate protein cross-links that are melanoidins, and possible deconvolution of the chemistry of melanoidin from these data. Further studies by Hofmann (1998a) proposed a cross-link structure BISARG, which was formed on reaction of N-protected arginine with glyoxal and furan-2-carboxaldehyde (Figure 10.3). This cross-link was proposed as plausible in food systems due to the large amount of protein, furan-2-carboxaldehyde and glyoxal that may be present in food (Hofmann 1998a).

A lysine–lysine radical cation cross-link, CROSSPY (Figure 10.3C), has been isolated from a model protein cross-link system involving bovine serum albumin and glycoladehyde, followed by thermal treatment (Hofmann et al. 1999). CROSSPY was also shown to form from glyoxal, but only in the presence of ascorbic acid, supporting the suggestion that reductones are able to initiate radical cation mechanisms resulting in cross-links (Hofmann et al. 1999). EPR spectroscopy of dark-coloured bread crust revealed results that suggested CROSSPY was most likely associated with the browning bread crust (Hofmann et al. 1999).
Figure 10.3. Formation of a melanoidin-type colourants on reaction of (**A**) protein-bound lysine with furan-2-aldehyde (Hofmann 1998b); (**B**) two protein-bound arginine residues with glyoxal in the presence of carbonyl compound (Hofmann 1998a); (**C**) two protein-bound lysine residues with glycolaldehyde or glyoxal (in the presence of ascorbate). R, remainder of carbonyl compound (Hofmann et al. 1999); (**D**) product of reaction of propylamine with glucose (Knerr et al. 2001); and (**E**) butylaminammonium acetate with glucose (Lerche et al. 2003).

Encouragingly, when browning was inhibited, radical formation was completely blocked.

A model system containing propylamine and glucose was found to yield a yellow cross-link product under food-processing conditions (Fig. 10.3D; Knerr et al. 2001); however, this product is still to be isolated from foodstuffs. In another model study undertaken by Lerche et al., reacting butylaminammonium acetate (a protein bound lysine mimic) with glucose resulted in the formation of a yellow product (Fig. 10.3E); this molecule is also still to be isolated from foodstuffs (Lerche et al. 2003).

The hypothesis that formation of melanoidins involves reaction of protein with carbohydrate is supported by Brands et al.,

who noted that following dialysis of a casein-sugar (glucose or fructose) system with 12,000 Da cutoff tubing, around 70% of the brown-coloured products were present in the retentate (Brands et al. 2002).

MAILLARD-RELATED CROSS-LINKS

Although not strictly classified under the heading of Maillard chemistry, animal tissues such as collagen and elastin contain complex heterocyclic cross-links, formed from the apparently spontaneous reaction of lysine and derivatives with allysine, an aldehyde formed from the oxidative deamination of lysine catalysed by the enzyme lysine oxidase (Feeney and Whitaker 1988). A selection of cross-links that form from this reaction is outlined in Figure 10.4. The extent to which these cross-links occur in food has not been well-studied, although their presence in gelatin has been discussed, along with the presence of pentosidine in these systems (Cole and Roberts 1996, 1997).

CROSS-LINKS FORMED VIA TRANSGLUTAMINASE CATALYSIS

An enzyme that has received extensive recent attention for its ability to cross-link proteins is transglutaminase. Transglutaminase catalyses the acyl-transfer reaction between the
Histidinohydroxylysinonorleucine
Hydroxypyridinium
(pyridinoline)

Figure 10.4. Trifunctional crosslinks reported to result from the spontaneous reaction of allysine with lysine (Eyre et al. 1984, Yamauchi et al. 1987, Brady and Robins 2001).

γ-carboxyamide group of peptide-bound glutamine residues and various primary amines. As represented in Figure 10.1, the ε-amino groups of lysine residues in proteins can act as the primary amine, yielding inter- and intramolecular ε-N-(γ-glutamyl)lysine cross-links (Zhu et al. 1995, Motoki and Seguro 1998, Yokoyama et al. 2004, Jaros et al. 2006, Özrenk 2006). The formation of this cross-link does not reduce the nutritional quality of the food as the lysine residue remains available for digestion (Seguro et al. 1996).

Transglutaminase is widely distributed in most animal tissues and body fluids and is involved in biological processes such as blood clotting and wound healing. ε-N-(γ-glutamyl)lysine cross-links can also be produced by severe heating (Motoki and Seguro 1998), but are most widely found where a food is processed from material that contains naturally high levels of the enzyme. The classic example here is the gelation of fish muscle in the formation of surumi products, a natural part of traditional food processing of fish by the Japanese suwari process, although the precise role of endogenous transglutaminase in this process is still under debate (An et al. 1996, Motoki and Seguro 1998) and an area of active research (Benjakul et al. 2004a, 2004b). ε-N-(γ-Glutamyl)lysine bonds have been found in various raw foods including meat, fish and shellfish. Transglutaminase-cross-linked proteins have thus long been ingested by man (Seguro et al. 1996). The increasing applications of artificially adding this enzyme to a wide range of processed foods, along with safety aspects, are discussed in detail below.

OTHER ISOPEPTIDE BONDS

In foods of low carbohydrate content, where Maillard chemistry is inaccessible, severe heat treatment can result in the formation of isopeptide cross-links during food processing, via condensation of the ε-amino group of lysine, with the amide group of an asparagine or glutamine residue (Singh 1991). This chemistry has not been widely studied in the context of food.

MANIPULATING PROTEIN CROSS-LINKING DURING FOOD PROCESSING

A major task of modern food technology is to generate new food structures with characteristics that please the consumer, using only a limited range of ingredients. Proteins are one of the main classes of molecule available to confer textural attributes, and the cross-linking and aggregation of protein molecules is an important mechanism for engineering food structures with desirable mechanical properties (Dickinson 1997, Oliver et al. 2006). The cross-linking of food proteins can influence many properties of food, including texture, viscosity, solubility, emulsification and gelling properties (Kuraishi et al. 2000, Motoki and Kumazawa 2000, Oliver et al. 2006). Many traditional food textures are derived from a protein gel, including those of yoghurt, cheese, sausage, tofu and surimi. Cross-linking provides an opportunity to create gel structures from protein solutions, dispersions, colloidal systems, protein-coated emulsion droplets or protein-coated gas bubbles and create new types of food or improve the properties of traditional ones (Dickinson 1997). In addition, judicious choice of starting proteins for cross-linking can produce food proteins of higher nutritional quality through cross-linking of different proteins containing complementary amino acids (Kuraishi et al. 2000).

CHEMICAL METHODS

An increasing understanding of the chemistry of protein cross-linking opens up opportunities to control these processes during food processing. Many commercial cross-linking agents are available, for example from Pierce (2001). These are usually double-headed reagents developed from molecules that derivatise the side chains of proteins (Matheis and Whitaker 1987, Feeney and Whitaker 1988) and generally exploit the lysine and/or cysteine residues of proteins in a specific manner. Doubt has been cast as to the accuracy with which reactivity of these reagents can be predicted (Green et al. 2001) but they remain widely used for biochemical and biotechnological applications.

Unfortunately, these reagents are expensive and not often approved for food use, so their use has not been widely explored (Singh 1991). They do, however, prove useful for 'proof of principle' studies to measure the possible effects of introducing specific new cross-links into food. If an improvement in functional properties is seen after treatment with a commercial cross-linking agent, then further research effort is merited to find a food approved, cost-effective means by which to introduce such cross-links on a commercial scale. Such 'proof of principle' studies include the use of glutaraldehyde to demonstrate the potential effects of controlled Maillard cross-linking on the texture of wheat-based foods (Gerrard et al. 2002, 2003a, 2003b). The cross-linking of hen egg white lysozyme with a double-headed reagent has also been used to show that the protein is rendered more stable to heat and enzyme digestion, with the foaming and emulsifying capacity reduced (Matheis and Whitaker 1987, Feeney and Whitaker 1988). Similarly, milk proteins cross-linked with formaldehyde showed greater heat stability (Singh 1991).

Food preparation for consumption often involves heating, which can result in a deterioration of the functional properties of these proteins (Bouhallab et al. 1999, Morgan et al. 1999a, Shepherd et al. 2000). In an effort to protect them from denaturation, particularly in the milk processing industry, some have harnessed the Maillard reaction to produce more stable proteins following incubation with monosaccharide (Aoki et al. 1999, Bouhallab et al. 1999, 2001, Handa and Kuroda 1999, Morgan et al. 1999a, Shepherd et al. 2000, Chevalier et al. 2001, Matsudomi et al. 2002). Increases in protein stability at high temperatures and improved emulsifying activity have been observed (Aoki et al. 1999, Bouhallab et al. 1999, Shepherd et al. 2000), and dimerisation and oligomerisation of these proteins has been noted (Aoki et al. 1999, Bouhallab et al. 1999, Morgan et al. 1999a, Pellegrino et al. 1999, Chevalier et al. 2001, French et al. 2002). In β-lactoglobulin, it has been suggested that oligomerisation is initiated by glycation of a β-lactoglobulin monomer, resulting in a conformational change in this protein

that engenders a propensity to form stable covalent homodimers (Morgan et al. 1999b). From this point, it is thought that polymerisation occurs *via* hydrophobic interactions between unfolded homodimers and modified monomers (Morgan et al. 1999b). Experiments undertaken by Bouhallab et al. (1999) showed that this final polymerisation process was not due to intermolecular cross-linking via the Maillard reaction, but did confirm that increased solubility of the protein at high temperatures (65–90°C) was associated with polymerisation, presumably invoking disulfide linkages. Some recent data, however, suggests that Maillard cross-links may also be important in the polymerisation process (Chevalier et al. 2001). Interestingly, Pellegrino et al. have observed that an increase in pentosidine formation coincided with heat-induced covalent aggregation of β-casein, which lacks cysteine, but could not account for the extent of aggregation observed, suggesting the presence of other cross-links that remain undefined (Pellegrino et al. 1999).

The glycation approach has also been also employed as a tool to improve gelling properties of dried egg white (Handa and Kuroda 1999, Matsudomi et al. 2002), a protein which is used in the preparation of surimi and meat products (Weerasinghe et al. 1996, Chen 2000, Hunt et al. 2009). Some have suggested that the polymerisation may occur via protein cross-links formed as a result of the Maillard reaction, but disulfide bonds may still play some role (Handa and Kuroda 1999); the exact mechanism remains undefined (Matsudomi et al. 2002).

The effect of the Maillard reaction and particularly protein cross-linking on food texture has received some attention (Gerrard et al. 2002a). Introduction of protein cross-links into baked products has been shown to improve a number of properties that are valued by the consumer (Gerrard et al. 1998b, 2000). In situ studies revealed that following addition of glutaraldehyde to dough, albumin and globulin fraction of the extracted wheat proteins were cross-linked (Gerrard et al. 2003a). Inclusion of glutaraldehyde during bread preparation resulted in the formation of a dough with an increased dough relaxation time, relative to the commonly used flour improver ascorbic acid (Gerrard et al. 2003b). These results confirm that chemical cross-links are important in the process of dough development and suggest that they can be introduced via Maillard-type chemistry.

The Maillard reaction has also been used to modify properties in tofu. Kaye et al. (2001) reported that following incubation with glucose, a Maillard network formed within the internal structure of tofu, resulting in a loss in tofu solubility and a reduction in tofu weight loss. Furthermore, Kwan and Easa (2003) employed low levels of glucose for the preparation of retort tofu, which resulted in the production of firmer tofu product. Changes in tofu structure have also been observed in our laboratory when including glutaraldehyde, glyceraldehyde or formaldehyde in tofu preparation (Yasir et al. 2007a, 2007b). However, these results suggested that protein cross-linking agents may change the functional properties of tofu via non-cross-linking modifications of the side chains of the amino acid residues, perhaps by changing their isoelectric point and gelation properties.

Caillard et al. (2008) have also observed interesting results with soy protein that forms hydrogels in the presence of the cross-linking agents glutaraldehyde and glyceraldehyde. Their studies found that glutaraldehyde was the more efficient cross-linker, because it was able to form stronger hydrogels with modifiable properties than glyceraldehyde. More recently, Caillard et al. (2009) investigated the photophysical and microstructural properties of soy protein hydrogels cross-linked with glutaraldehyde in the absence or presence of salts.

The covalent polymerisation of milk during food processing has been reported (Singh and Latham 1993). This phenomenon was shown to be sugar dependent, as determined in model studies with β-casein. Further, pentosidine formation paralleled protein aggregation over time at 70°C (Pellegrino et al. 1999).

The Maillard reaction has been studied under dry conditions to gain an understanding of the details of the chemistry (Kato et al. 1988, French et al. 2002, Oliver et al. 2006). Kato et al. (1986b) reported the formation of protein polymers following incubation of galactose or talose with ovalbumin under desiccating conditions: an increase in polymerisation, relative to the protein only control, was observed. This study was extended using the milk sugar lactose, as milk can often be freeze dried for shipping and storage purposes. In this study, it was shown, in a dry reaction mixture, that ovalbumin was polymerised following incubation with lactose and glucose (Kato et al. 1988). In model studies with the milk protein β-lactoglobulin, the formation of protein dimers has been observed on incubation with lactose (French et al. 2002).

Proof of principle has thus been obtained in several systems, demonstrating that reactive cross-linking molecules are able to cross-link food proteins within the food matrix and lead to a noticeable change in the functional properties of the food. However, much work remains to be done in order to generate sufficient quantities of cross-linking intermediates during food processing to achieve a controlled change in functionality.

Enzymatic Methods

The use of enzymes to modify the functional properties of foods is an area that has attracted considerable interest, since consumers perceive enzymes to be more "natural" than chemicals. Enzymes are also favoured as they require milder conditions, have high specificity, are only required in catalytic quantities, and are less likely to produce toxic products (Singh 1991). Thus, enzymes are becoming commonplace in many industries for improving the functional properties of food proteins (Chobert et al. 1996, Poutanen 1997, Oliver et al. 2006, Hiller and Lorenzen 2009).

Because of the predominance of disulfide cross-linkages in food systems, enzymes that regulate disulfide interchange reactions are of interest to food researchers. One such enzyme is protein disulfide isomerase (PDI; Hatahet and Ruddock 2009). PDI catalyses thiol/disulfide exchange, rearranging 'incorrect' disulfide cross-links in a number of proteins of biological interest (Hillson et al. 1984, Singh 1991, Hatahet and Ruddock 2009). The reaction involves the rearrangement of low molecular sulfhydryl compounds (e.g. glutathione, cysteine and dithiothreitol) and protein sulfhydryls. It is thought to proceed by the transient breakage of the protein disulfide bonds by the enzyme and the reaction of the exposed active cysteine sulfhydryl groups

with other appropriate residues to reform native linkages (Singh 1991).

PDI has been found in most vertebrate tissues and in peas, cabbage, yeast, wheat and meat (Singh 1991). It has been shown to catalyse the formation of disulfide bonds in gluten proteins synthesised in vitro. Early reports suggested that a high level of activity corresponded to a low bread-making quality (Grynberg et al. 1977). The use of oxidoreduction enzymes, such as PDI, to improve product quality is an area of interest to the baking industry (Watanabe et al. 1998, van Oort 2000, Joye et al. 2009a, 2009b) and the food industry in general (Hjort 2000). The potential of enzymes such as PDI to catalyse their interchange has been extensively reviewed by Shewry and Tatham (1997).

Sulfhydryl (or thiol) oxidase catalyses the oxidative formation of disulfide bonds from sulfhydryl groups and oxygen and occurs in milk (Matheis and Whitaker 1987, Singh 1991). Immobilised sulfhydryl oxidase has been used to eliminate the 'cooked' flavour of ultra-high temperature-treated milk (Swaisgood 1980). It is not a well-studied enzyme, although the enzyme from chicken egg white has received recent attention in biology (Hoober 1999). Protein disulfide reductase catalyses a further sulfhydryl–disulfide interchange reaction and has been found in liver, pea and yeast (Singh 1991).

Peroxidase, lipoxygenase and catechol oxidase occur in various plant foods and are implicated in the deterioration of foods during processing and storage. They have been shown to cross-link several food proteins, including bovine serum albumin, casein, β-lactoglobulin and soy, although the uncontrolled nature of these reactions casts doubt on their potential for food improvement (Singh 1991). Lipoxygenase, in soy flour, is used in the baking industry to improve dough properties and baking performance. It acts on unsaturated fatty acids, yielding peroxy free radicals and starting a chain reaction. The cross-linking action of lipoxygenase has been attributed to both the free radical oxidation of free thiol groups to form disulfide bonds and to the generation of reactive cross-linking molecules such as malondialdehyde (Matheis and Whitaker 1987).

Altering the functional properties of milk proteins by cross-linking with transglutaminase (see below), as well as the enzymes lactoglutaminase, lactoperoxidase, laccase and glucose oxidase has recently been studied by Hiller and Lorenzen (2009). In this study, a qualitative and quantitative overview of the enzymatic oligomerisation of milk proteins by various enzymes in relation to transglutaminase was presented, to fill a gap in understanding of enzymatic oligomerisation of proteins. A variety of milk proteins were chosen for this study, such as sodium caseinate, whey protein isolate and skim milk powder. Interestingly, the results from this study suggest it may be possible to specifically select the appropriate modified protein to use for specific industrial applications, depending upon the requirements of the food proteins and the desired functional protein properties.

All enzymes discussed so far have been over-shadowed in recent years by the explosion in research on the enzyme transglutaminase. Due largely to its ability to induce the gelation of protein solutions, transglutaminase has been investigated for uses in a diverse range of foods and food-related products. The use of this enzyme has been the subject of a series of recent reviews, covering both the scientific and patent literature (Nielson 1995, Zhu et al. 1995, Motoki and Seguro 1998, Kuraishi et al. 2001, Yokoyama et al. 2004, Jaros et al. 2006, Özrenk 2006). These are briefly highlighted below.

Transglutaminase

The potential of transglutaminase in food processing was hailed for many years before a practical source of the enzyme became widely available. The production of a microbially derived enzyme by Ajinomoto Inc. proved pivotal in paving the way for industrial applications (Motoki and Seguro 1998). In addition, the transglutaminases that were discovered in the early years were calcium-ion dependent, which imposed a barrier for their use in foods that did not contain a sufficient level of calcium. The commercial preparation is not calcium dependent and thus finds much wider applicability (Motoki and Seguro 1998). The production of microbial transglutaminase, derived from *Streptoverticillium mobaraense,* is described by Zhu et al. (1995) and methods with which to purify and assay the enzyme are reviewed by Wilhelm et al. (1996). The commercial enzyme operates effectively over the pH range 4–9, from 0°C to 50°C (Motoki and Seguro 1998).

There is a seemingly endless list of foods in which the use of transglutaminase has been successfully used (De Jong and Koppelman 2002): seafood, surimi, meat, dairy (Hiller and Lorenzen 2009), baked goods, sausages (as a potential replacement for phosphates and other salts), gelatin (Kuraishi et al. 2001), spaghetti (Aalami and Leelavathi 2008), noodles and pasta (Larre et al. 1998, 2000). It is finding increasing use in restructured products, such as those derived from scallops and pork (Kuraishi et al. 1997). In all cases, transglutaminase is reported to improve firmness, elasticity, water-holding capacity and heat stability (Kuraishi et al. 2001). It also has potential to alleviate the allergenicity of some proteins (Watanabe et al. 1994). Dickinson (1997) reviewed the application of transglutaminase to cross-link different kinds of colloidal structures in food and enhance their solid-like character in gelled and emulsified systems, controlling rheology and stability. These applications are particularly appealing in view of the fact that cross-linking by transglutaminase is thought to protect nutritionally valuable lysine residues in food from various deteriorative reactions (Seguro et al. 1996). Furthermore, the use of transglutaminase potentially allows production of food proteins of higher nutritional quality, through cross-linking of different proteins containing complementary amino acids (Zhu et al. 1995).

The use of transglutaminase in the dairy industry has been explored extensively. The enzyme has been trialled in many cheeses, from Gouda to Quark, and the use of transglutaminase in ice cream is reported to yield a product that is less icy and more easily scooped (Kuraishi et al. 2001). Milk proteins form emulsion gels that are stabilised by cross-linking, opening new opportunities for protein-based spreads, desserts and dressings (Dickinson and Yamamoto 1996). The use of transglutaminase has been explored in an effort to improve the functionality of whey proteins (Truong et al. 2004, Gauche et al. 2008, 2010), for

example recent developments include the use of transglutaminase to incorporate whey protein into cheese (Cozzolino et al. 2003, Pereira et al. 2009) and yoghurt (Ozer et al. 2007, Gauche et al. 2009).

Soy products have also benefited from the introduction of transglutaminase, with the enzyme providing manufacturers with a greater degree of texture control. The enzyme is reported to enhance the quality of tofu made from old crops, giving a product with increased water-holding capacity, a good consistency, a silky and firmer texture and one that is more robust in the face of temperature change (Kuraishi et al. 2001, Soeda 2003). Transglutaminase has also been used to incorporate soy protein into new products, such as chicken sausages (Muguruma et al. 2003). More recent studies have found that transglutaminase can potentially reduce the extent of the Maillard reaction and cross-links (Gan et al. 2009). Soy protein isolate that had been heated in the presence of transglutaminase to initiate the ε-(γ-glutamyl)lysine bonds formed were then heated in the presence of ribose to initiate Maillard reaction. It was found that the ε-(γ-glutamyl)lysine bonds formed during incubation of soy protein isolate with transglutaminase reduced the number of free amino groups able to take part in the following Maillard reaction with ribose. Consequently, the use of transglutaminase is most likely to be most beneficial in products that contain reducing sugars, where it is advantageous for the Maillard reaction to be limited.

New foods are being created using transglutaminase, for example, imitation shark fin for the South East Asian market has been generated by cross-linking gelatin and collagen (Zhu et al. 1995). Cross-linked proteins have also been tested as fat substitutes in products such as salami and yoghurt (Nielson 1995) and the use of transglutaminase-cross-linked protein films as edible films has been patented (Nielson 1995).

Not surprisingly, the rate of cross-linking by transglutaminase depends on the particular structure of the protein acting as substrate. Most efficient cross-linking occurs in proteins that contain a glutamine residue in a flexible region of the protein or within a reverse turn (Dickinson 1997). Casein is a very good substrate, but globular proteins such as ovalbumin and β-lactoglobulin are poor substrates (Dickinson 1997). Denaturation of proteins increases their reactivity, as does chemical modification by disruption of disulfide bonds or by adsorption at an oil–water interface (Dickinson 1997). Many of the reported substrates of transglutaminase have actually been acetylated and/or denatured with reagents such as dithiothreitol under regimes that are not food approved (Nielson 1995). More work needs to be done to find ways to modify certain proteins in a food-allowed manner in order to render them amenable to cross-linking by transglutaminase in a commercial setting.

Whilst the applications of transglutaminase have been extensively reported in the scientific and patent literature, the precise mode of action of the enzyme in any one food processing situation remains relatively unexplored. The specificity of the enzyme suggests that in mixtures of food proteins, certain proteins will react more efficiently than others, and there is value in understanding precisely which protein modifications exert the most desirable effects. Additionally, transglutaminase has more than one activity: as well as cross-linking, the enzyme may catalyse the incorporation of free amines into proteins by attachment to a glutamine residue. Furthermore, in the absence of free amine, water becomes the acyl acceptor and the γ-carboxamide groups are deamidated to glutamic acid residues (Ando et al. 1989). The extent of these side reactions in foods, and the consequences of any deamidation to the functionality of food proteins, has yet to be fully explored. However, there have been suggestions that in the case of wheat proteins, these side reactions may lead to unwanted consequences, specifically associated with the celiac response (Gerrard and Sutton 2005, Leszczynska et al. 2006, Cabrera-Chavez et al. 2008), and the use in wheat products is not advised until further research has been done to investigate this possibility.

Perhaps the most advanced understanding of the specific molecular effects of transglutaminase in a food product is seen in yoghurt, where the treated product has been analysed by gel electrophoresis and specific functional effects correlated to the loss of β-casein, with the α-casein remaining. The specificity of the reaction was found to alter according to the exact transglutaminase source (Kuraishi et al. 2001). The specific effects of transglutaminase in baked goods (Gerrard et al. 1998b, 2000) have also been analysed at a molecular level. In particular, the enzyme produced a dramatic increase in the volume of croissants and puff pastries, with desirable flakiness and crumb texture (Gerrard et al. 2001). These effects were later correlated with cross-linking of the albumins and globulins and high-molecular weight glutenin fractions by transglutaminase (Gerrard et al. 2001). Subsequent research suggested that the dominant effect was attributable to cross-linking of the high-molecular weight glutenins (Gerrard et al. 2002). However, as noted above, the use of transglutaminase for wheat-based produce is not recommended (Gerrard and Sutton 2005).

FUTURE APPLICATIONS OF PROTEIN CROSS-LINKING

Although protein cross-linking is often considered to be detrimental to the quality of food, it is increasingly clear that it can also be used as a tool to improve food properties. The more we understand of the chemistry and biochemistry that take place during processing, the better placed we are to exploit it – minimising deleterious reactions and maximising beneficial ones.

Food chemists are faced with the task of understanding the vast array of reactions that occur during the preparation of food. Food often has complex structures and textures, and through careful manipulation of specific processes that occur during food preparation, these properties can be enhanced to generate a highly marketable product (Dickinson 1997). The formation of a structural network within food is critical for properties such as food texture. From a biopolymer point of view, this cross-linking process has been successfully applied in the formation of protein films, ultimately for use as packaging. Enhancing textural properties, emulsifying and foaming properties, by protein cross-linking has been a subject of interest of many working in this area, as exemplified by the number of studies detailed above.

Cross-linking using chemical reagents remains challenging, both in terms of controlling the chemistry and gaining consumer acceptance. However, as the extensive recent use of transglutaminase dramatically illustrates, protein cross-linking using enzymes has huge potential for the improvement of traditional products and the creation of new ones. Transglutaminase itself will no doubt find yet more application as its precise mode of action becomes better understood, especially if variants of the enzyme are found with a broader substrate specificity.

Whether other enzymes, which cross-link by different mechanisms, can find equal applicability remains open to debate. The thiol exchange enzymes, such as PDI, may offer advantages to food processors if their mechanisms can be unravelled, and then controlled within a foodstuff. Other enzymes, such as lysyl oxidase, have not yet been used, but have potential to improve foods (Dickinson 1997), especially in the light of recent work characterising this class of enzymes (Buffoni and Ignesti 2000), which may allow their currently unpredictable effects to be better understood.

Chymosin in Cheese Making

V. V. Mistry

INTRODUCTION

Cheeses are classified into those that are aged for the development of flavor and body over time and those that are ready for consumption shortly after manufacture. Many cheese varieties are also expected to develop certain functional characteristics either immediately after manufacture or by the end of the aging period. It is fascinating that what starts in the cheese vat, as a white liquid that is composed of many nutrients, emerges as a completely transformed compact mass, cheese, sometimes

colored yellow, sometimes white, and sometimes with various types of mold on the surface or within the cheese mass (Kosikowski and Mistry 1997). Some cheeses may also exhibit a unique textural character that turns stringy when heated, and others may have shiny eyes. Each cheese also has unique flavor qualities. Thus, cheese is a complex biological material whose characteristics are specifically tailored by the cheese maker through judicious blends of enzymes, starter bacteria, acid, and temperature.

Milk is a homogeneous liquid in which components exist in soluble, emulsion, or colloidal form. The manufacture of cheese involves a phase change from liquid (milk) to solid (cheese). This phase change occurs under carefully selected conditions that alter the physicochemical environment of milk such that the milk system is destabilized and is no longer homogeneous. In many fresh cheeses, this conversion takes place with the help of acid through isoelectric precipitation of casein and subsequent temperature treatments and draining for the conversion of liquid to solid. In the case of most ripened cheeses, this conversion occurs enzymatically at higher pH and involves the transformation of the calcium paracaseinate complex through controlled lactic acid fermentation. Later on, the products of this reaction and starter bacteria interact for the development of flavor and texture. All this is the result of the action of the enzyme chymosin (Andren 2003).

CHYMOSIN

Chymosin, rennet, and rennin are often used interchangeably to refer to this enzyme. The latter, rennin, should not be confused with renin, which is an enzyme associated with kidneys and does not clot milk. Chymosin is the biochemical name of the enzyme that was formerly known as rennin. It belongs to the group of aspartic acid proteinases, Enzyme classification (EC) 3.4.23, that have a high content of dicarboxylic and hydroxyamino acids and

a low content of basic amino acids. Its molecular mass is 40 kDa (Andren 2003, Foltmann 1993).

Rennet is the stomach extract that contains the enzyme chymosin in a stabilized form that is usable for cheese making (Green 1977). While the amount of chymosin that is required for cheese making is very small, this enzyme industry has undergone an interesting transformation over time. It is believed that in the early days of cheese making, milk coagulation occurred either by filling dried stomachs of calves or lambs with milk or by immersing pieces of such stomachs in milk (Kosikowski and Mistry 1997). The chymosin enzyme embedded within the stomach lining diffused into the milk and coagulated it. This crude process of extracting coagulating enzymes was eventually finessed into an industry that employed specific methods to extract and purify the enzyme and develop an extract from the fourth stomach of the calf or lamb. Extracts of known enzyme activity and predictable milk clotting properties then became available as liquids, concentrates, powders, and blends of various enzymes. Live calves were required for the manufacture of these products. Because of religious and economic reasons, another industry also had emerged for manufacturing alternative milk clotting enzymes from plants, fungi, and bacteria. These products remain popular and meet the needs of various Kosher and other religious needs. Applications of genetic technology in rennet manufacture were then realized, and in 1990 a new process utilizing this technology was approved in the United States for manufacturing rennet.

RENNET MANUFACTURE

For the manufacture of traditional rennet, calves, lambs, or kids that are no more than about 2-weeks-old and fed only milk are used (Kosikowski and Mistry 1997). As calves become older and begin eating other feeds, the proportion of bovine pepsin in relation to chymosin increases. Extracts from milk-fed calves that are 3-weeks-old contain over 90% chymosin, and the balance is pepsin. As the calves age and are fed other feeds such as concentrates, the ratio of chymosin to pepsin drops to 30:70 by 6 months of age. In a full-grown cow, there are only traces of chymosin.

Milk-fed calves are slaughtered, and the unwashed stomachs (vells) are preserved for enzyme extraction by emptying their contents, blowing them into small balloons and drying them. The vells may also be slit opened and dry salted or frozen for preservation. Air-dried stomachs give lower yields of chymosin than frozen stomachs; 12–13 air-dried stomachs make 1 L of rennet standardized to 1:10,000 strength, but only 7–8 frozen stomachs would be required for the same yield.

Extraction of chymosin and production of rennet begin by extracting, for several days, chopped or macerated stomachs with a 10% sodium chloride solution containing about 5% boric acid or glycerol. Additional salt up to a total of 16–18% is introduced followed by filtration and clarification. Mucine and grass particles in suspension are removed by introducing 1% of potash alum, followed by an equal amount of potassium phosphate. The suspension is adjusted to pH 5.0 to activate prochymosin (zymogen) to chymosin, and the enzyme strength is standardized, so that one part coagulates 15,000 or 10,000 parts of milk. Sodium benzoate, propylene glycol, and salt are added as preservatives for the final rennet. Caramel color is also usually added. The finished rennet solutions must be kept cold and protected from light.

Powdered rennet is manufactured by saturating a rennet suspension with sodium chloride or acidifying it with a food-grade acid. Chymosin precipitates and secondary enzymes such as pepsin remain in the original suspension. The chymosin-containing precipitate is dried to rennet powder (Kosikowski and Mistry 1997).

A method has been developed for manufacturing rennet without slaughtering calves. A hole (fistula) is surgically bored in the side of live calves, and at milk feeding time, excreted rennet is removed. After the calf matures, the hole is plugged, and the animal is returned to the herd. This method has not been commercialized but may be of value where religious practices do not allow calf slaughter.

Rennet paste, a rich source of lipolytic enzymes, has been a major factor in the flavor development of ripened Italian cheeses such as Provolone and Romano. Conceivably, 2100 years ago, Romans applied rennet paste to cheese milks to develop a typical "picante" flavor in Romano and related cheeses, for even then calf rennet was used to set their cheese milks. In more modern times, many countries, including the United States, applied calf rennet paste to induce flavor, largely for Italian ripened cheeses.

Farntiam et al. (1964) successfully produced, from goats, dried preparations of a pregastric-oral nature, also rich in lipolytic enzymes. They applied them to milk for ripened Italian cheese with excellent results. Since then, lipase powders, of various character and strength, have largely replaced rennet paste.

CHYMOSIN PRODUCTION BY GENETIC TECHNOLOGY

Genetic technology has been used for the commercial production of a 100% pure chymosin product from microbes. This type of chymosin is often called fermentation-produced chymosin. Uchiyama et al. (1980) and Nishimori et al. (1981) published early on the subject, and in 1990 Pfizer, Inc., received US Food and Drug Administration approval to market a genetically transformed product, Chy-Max, with GRAS stature (Duxbury 1990). Other brands using other microorganisms have also been approved. Table 11.1 lists some examples of such products.

The microbes used for this type of rennet include nonpathogenic microorganisms *Escherichia coli* K-12, *Kluyveromyces marxianus* var. *lactis* and *Aspergillus niger* var. *awamori*. Prochymosin genes obtained from young calves are transferred through DNA plasmid intervention into microbial cells. Fermentation follows to produce prochymosin, cell destruction, activation of the prochymosin to chymosin, and harvesting/producing large yields of pure, 100% chymosin. This product, transferred from an animal, is considered a plant product, as microbes are of the plant kingdom. Thus, they are acceptable to various religious groups.

These products have been widely studied to evaluate their impact on the quality and yield of cheese. An initial concern was that because of the absence of pepsin from these types of

Table 11.1. Examples of Some New Chymosin Products

Product Name	Company and Type
AmericanPure	Sanofi Bio-Industries Calf rennet purified via ion exchange
Chy-max	Pfizer (Now Chr. Hansen) Fermentation—using *Escherichia coli* K-12
Chymogen	Chr. Hansen Fermentation—using *Aspergillus niger* var. *awamori*
ChymoStar	Rhône-Poulenc (Now Danisco) Fermentation—using *Aspergillus niger* var. *awamori*
Maxiren	Gist-Brocades Fermentation—using *Kluyveromyces marxianus* var. *lactis*
Novoren[a]	Novo Nordisk
(Marzyme GM)	Fermentation—using *Aspergillus oryzae*

[a]Novoren is not chymosin: it is the coagulating enzyme of *Mucor miehei* cloned into *A. oryzae*. The other products listed above are all 100% chymosin.

rennets, proper cheese flavor might not develop. Most studies have generally concluded that there are no significant differences in flavor, texture, composition, and yield compared with calf rennet controls (Banks 1992, Barbano and Rasmussen 1992, Biner et al. 1989, Green et al. 1985, Hicks et al. 1988, IDF 1992, Ortiz de Apodaca et al. 1994).

When these products were first introduced, it was expected that a majority of cheese makers would convert to these types of rennets because they are virtually identical to traditional calf rennet and much cheaper. Except for some areas, this has not generally happened because of some concerns toward genetically modified products. Further, some protected cheeses, such as those under French AOC regulations or Italian DOP regulations, require the use of only calf rennet. A method has been published by the International Dairy Federation to detect fermentation-produced chymosin (Collin et al. 2003). This method uses immunochemical techniques (ELISA) to detect such chymosin in rennet solutions. It cannot be used for cheese.

Thus, traditional calf rennet and rennet substitutes derived from *Mucor Miehei, Cryphonectria, Parasitica*, and others are still used, especially for high cooking temperature cheeses such as Swiss and Mozzarella. Since the introduction of fermentation chymosin, the cost of traditional calf rennet has dropped considerably, and they both now cost approximately the same. Fungal rennets are still available at approximately 65% of the cost of the recombinant chymosin.

A coagulating enzyme of *Mucor miehei* cloned into *Aspergillus oryzae* was developed by Novo Nordisk of Denmark. This product hydrolyzes kappa-casein only at the 105-106 bond, and reduces protein losses to whey.

RENNET PRODUCTION BY SEPARATION OF BOVINE PEPSIN

Traditional calf rennet contains about 5% pepsin and almost 95% chymosin. Industrial purification of standard rennet to 100% chymosin rennet by the removal of pepsin was developed by Sanofi-Bioingredients Co. The process involves separation of the pepsin by ion exchange. Chymosin has no charge at pH 4.5, but bovine pepsin is negatively charged. Traditional commercial calf rennet is passed through an ion-exchange column containing positively charged ions. Bovine pepsin, due to its negative charge, is retained, and chymosin passes through and is collected, resulting in a 100% chymosin product (Pszczola 1989).

RENNET SUBSTITUTES

Improved farming practices, including improved genetics, have led over the years to significant increases in the milk production capacity of dairy cattle. As a result, while total milk production in the world has increased, the total cow population has declined. Hence, there has been a reduction in calf populations and the availability of traditional calf rennet. Furthermore, the increased practice of raising calves to an older age for meat production further reduced the numbers available for rennet production. It is for these reasons that a shortage of calf rennet occurred and substitutes were sought. Various proteolytic enzymes from plant, microbial, and animal sources were identified and developed for commercial applications. These enzymes should possess certain key characteristics to be successful rennet substitutes: (1) the clotting-to-proteolytic ratio should be similar to that of chymosin (i.e., the enzyme should have the capacity to clot milk without being excessively proteolytic); (2) the proteolytic specificity for beta-casein should be low because otherwise bitterness will occur in cheese; (3) the substitute product should be free of contaminating enzymes such as lipases; and (4) cost should be comparable to or lower than that of traditional rennet.

ANIMAL

Pepsin derived from swine shows proteolytic activity between pH 2 and 6.5, but by itself it has difficulty in satisfactorily coagulating milk at pH 6.6. For this reason, it is used in cheese making as a 1:1 blend with rennet. Pepsin, used alone as a milk coagulator, shows high sensitivity to heat and is inclined to create bitter cheese if the concentrations added are not calculated and measured exactly (Kosikowski and Mistry 1997).

PLANT

Rennet substitutes from plant sources are the least widely used because of their tendency to be excessively proteolytic and to cause formation of bitter flavors. Most such enzymes are also heat stable and require higher setting temperatures in milk. Plant sources include ficin from the fig tree, papain from the papaya tree, and bromelin from pineapple. A notable exception to these problems is the proteolytic enzymes from the flower of thistle *(Cynara Cardunculus)*, as reported by Vieira de Sa and Barbosa

(1970) and *Cynara humilis* (Esteves and Lucey 2002). These enzymes have been used successfully for many years in Portugal to make native ripened Serra cheese with excellent flavor and without bitterness.

In India, enzymes derived from *Withania coagulans* have been used successfully for cheese making, but commercialization has been minimal, especially with the development of genetically derived chymosin.

Microbial

Substitutes from microbial sources have been very successful and continue to be used. Many act like trypsin and have an optimum pH activity between 7 and 8 (Green 1977, Kosikowski and Mistry 1997). Microorganisms, including *Bacillus subtilis*, *B. cereus*, *B. polymyxa*, *Cryphonectria parasitica* (formerly *Endothia parasitica*), and *Mucor pusillus* Lindt (also known as *Rhizomucor pusillus)* and *Rh. miehei* have been extracted for their protease enzymes. The bacilli enzyme preparations were not suited for cheese making because of excessive proteolytic activity while the fungal-derived enzymes gave good results, but not without off flavors such as bitter. Commercial enzyme preparations isolated from *Cr. parasitica* led to good quality Emmental cheese without bitter flavor, but some cheeses, such as Cheddar, that use lower cooking temperatures reportedly showed bitterness. Enzyme preparations of *Rh. Miehei*, at recommended levels, produced Cheddar and other hard cheeses of satisfactory quality without bitter flavor. Fungal enzyme preparations are in commercial use, particularly in North America. In cottage cheese utilizing very small amounts of coagulating enzymes, shattering of curd was minimum in starter-rennet set milk and maximum in starter–microbial milk coagulating enzyme set milk (Brown 1971).

Enzymes derived from *Rh. miehei* and *Rh. pusillus* are not inactivated by pasteurization. Any residual activity in whey led to hydrolysis of whey proteins during storage of whey powder. This problem has been overcome by treating these enzymes with peroxides to reduce heat stability. Commercial preparations of *Rh. miehei* and *Rh. pusillus* are inactivated by pasteurization. The heat stability of *Cr. parasitica*–derived enzyme is similar to that of chymosin.

These fungal enzymes are also milk-clotting aspartic enzymes, and all except *Cr. parasitica* clot milk at the same peptide bond as chymosin. *Cryphonectria* clots kappa-casein at the 104-105 bond.

CHYMOSIN ACTION ON MILK

Chymosin produces a smooth curd in milk, and it is relatively insensitive to small shifts in pH that may be found in milk due to natural variations, does not cause bitterness over a wide range of addition, and is not proteolytically active if the cheese supplements other foods. Chymosin coagulates milk optimally at pH 6.0–6.4 and at 20–30°C in a two-step reaction, although the optimum pH of the enzyme is approximately 4 (Kosikowski and Mistry 1997, Lucey 2003). Optimum temperature for coagulation is approximately 40°C, but milk for cheese making

is coagulated with rennet at 31–32°C because at this temperature the curd is rheologically most suitable for cheese making. Above pH 7.0, activity is lost. Thus, mastitic milk is only weakly coagulable, or does not coagulate at all.

Chymosin is highly sensitive to shaking, heat, light, alkali, dilutions, and chemicals. Stability is highest when stored at 7°C and pH 5.4–6.0 under dark conditions. Liquid rennet activity is destroyed at 55°C, but rennet powders lose little or no activity when exposed to 140°C. Standard single-strength rennet activity deteriorates at about 1% monthly when held cold in dark or plastic containers.

Single-strength rennet is usually added at 100–200 mL per 1000 kg of milk. It serves to coagulate milk and to hydrolyze casein during cheese ripening for texture and flavor development.

It should be noted that bovine chymosin has greater specificity for cow's milk than chymosin derived from kid or lamb. Similarly, kid chymosin is better suited for goat milk.

Milk contains fat, protein, sugar, salts, and many minor components in true solution, suspension, or emulsion. When milk is converted into cheese, some of these components are selectively concentrated as much as ten fold, but some are lost to whey. It is the fat, casein, and insoluble salts that are concentrated. The other components are entrapped in the cheese serum or whey, but only at about the levels at which they existed in the milk. These soluble components are retained, depending on the degree that the serum or whey is retained in the cheese. For example, in a fresh Cheddar cheese, the serum portion is lower in volume than in milk. Thus, the soluble component percentage of the cheese is smaller.

In washed curd cheeses such as Edam or Brick, the above relationship does not hold, and lactose, soluble salts, and vitamins in the final cheese are reduced considerably. Approximately 90% of living bacteria in the cheese-milk, including starter bacteria, are trapped in the cheese curd. Natural milk enzymes and others are, in part, preferentially absorbed on fat and protein, and thus a higher concentration remains with the cheese. In rennet coagulation of milk and the subsequent removal of much of the whey or serum, a selective separation of the milk components occurs, and in the resulting concentrated curd mass, many biological agents become active, marking the beginning of the final product, cheese.

Milk for ripened cheese is coagulated at a pH above the isoelectric point of casein by special proteolytic enzymes, which are activated by small amounts of lactic acid produced by added starter bacteria. The curds are sweeter and more shrinkable and pliable than those of fresh, unripened cheeses, which are produced by isoelectric precipitation. These enzymes are typified by chymosin that is found in the fourth stomach, or abomasum, of a young calf.

The isoelectric condition of a protein is that at which the net electric charge on a protein surface is zero. In their natural state in milk, caseins are negatively charged, and this helps maintain the protein in suspension. Lactic acid neutralizes the charge on the casein. The casein then precipitates as a curd at pH 4.6, the isoelectric point, as in cottage or cream cheese and yogurt. For some types of cheeses, this type of curd is not desirable because it would be too acid, and the texture would be too firm

and grainy. For ripened cheeses such as Cheddar and Swiss, a sweeter curd is desired, so casein is precipitated as a curd near neutrality, pH 6.2, by chymosin in 30–45 minutes at 30–32°C. This type of curd is significantly different than isoelectric curd and much more suitable for ripened cheeses. Milk proteins other than casein are not precipitated by chymosin. The uniform gel formed is made up of modified casein with fat entrapped within the gel.

MILK COAGULATION AND PROTEIN HYDROLYSIS BY CHYMOSIN

The process of curd formation by chymosin is a complex process and involves various interactions of the enzyme with specific sites on casein, temperature and acid conditions, and calcium. Milk is coagulated by chymosin into a smooth gel capable of extruding whey at a uniformly rapid rate. Other common proteolytic enzymes such as pepsin, trypsin, and papain coagulate milk too, but may cause bitterness and loss of yield and are more sensitive to pH and temperature changes.

An understanding of the structure of casein in milk has contributed to the explanation of the mechanism of chymosin action in milk. Waugh and von Hippel (1956) began to unravel the heterogeneous nature of casein with their observations on kappa-casein. Casein comprises 45–50% alpha-s-casein, 25–35% beta-casein, 8–15% kappa-casein, and 3–7% gamma-casein. Various subfractions of alpha-casein have also been identified, as have genetic variants. Each casein fraction differs in sensitivity to calcium, solubility, amino acid makeup, and electrophoretic mobility.

An understanding of the dispersion of casein in milk has provoked much interest. Several models of casein micelles have been proposed including the coat-core, internal structure, and subunit models. With the availability of newer analytical techniques such as three-dimensional X-ray crystallography, work on casein micelle modeling is continuing, and additional understanding is being gained. The subunit model (Rollema 1992) is widely accepted. It suggests that the casein micelle is made up of smaller submicelles that are attached by calcium phosphate bonds. Hence, the micelle consists of not only pure casein (∼93%), but also minerals (∼7%), primarily calcium and phosphate. Most of the kappa-casein is located on the surface of the micelle. This casein has few phosphoserine residues and hence is not affected by ionic calcium. It is located on the surface of the micelle and provides for stability of the micelle and protects the calcium-sensitive and hydrophobic interior, including alpha- and beta- caseins from ionic calcium. These two caseins have phosphoserine residues and high calcium-binding affinity. The carbohydrate, *N*-acetyl neuramic acid, which is attached to kappa-casein, makes this casein hydrophilic. Thus, the casein micelle is suspended in milk as long as the properties of kappa-casein remain unchanged. More recently the dual-bonding model has been proposed (Horne 1998).

Introducing chymosin to the cheese-milk, normally at about 32°C, destabilizes the casein micelle in a two-step reaction, the first of which is enzymatic (or primary) and the second, nonenzymatic (or secondary) (Kosikowski and Mistry 1997, Lucey
$$\text{kappa-Casein} \xrightarrow{\text{chymosin}} \textit{para}\text{-kappa-casein} + \text{glycomacropeptide (soluble in whey)}$$

$$\textit{para}\text{-kappa-Casein} \xrightarrow[\text{pH 6.4-6.0}]{\text{Ca}^{++}} \text{dicalcium para-kappa-casein}$$

Figure 11.1. Destabilization of the casein micelle by introduction of chymosin.

2003). These two steps are separate but cannot be visually distinguished: only the appearance of a curd signifies the completion of both steps. The primary phase was probably first observed by Hammersten in the late 1800s (Kosikowski and Mistry 1997) and must occur before the secondary phase begins.

In the primary phase, chymosin cleaves the phenylalanine-methionine bond (105–106) of kappa-casein, thus eliminating its stabilizing action on calcium-sensitive alpha-s- and beta-caseins. In the secondary phase, the micelles without intact kappa-casein aggregate in the presence of ionic calcium in milk and form a gel (curd). This mechanism may be summarized as follows (Fig. 11.1):

The macropeptide, also known as caseinmacropeptide, contains approximately 30% amino sugar, hence the name glycomacropeptide (Lucey 2003). In the ultrafiltration processes of cheese making, this macropeptide is retained with whey proteins to increase cheese yields significantly. In the conventional cheese-making process, the macropeptide is found in whey.

The two-step coagulation does not fully explain the presence of the smooth curd or coagulum. Beau, many years ago, established that a strong milk gel arose because the fibrous filaments of paracasein cross-linked to make a lattice. Bonding at critical points between phosphorus, calcium, free amino groups, and free carboxyl groups strengthened the lattice, with its entrapped lactose and soluble salts. A parallel was drawn between the gel formed when only lactic acid was involved as in fresh, unripened cheese and when considerable chymosin was involved as in hard, ripened cheese. Both gels were considered originally as starting with a fibrous protein cross bonding, but the strictly lactic acid curd was considered weaker, because not having been hydrolyzed by a proteolytic enzyme, it possessed less bonding material. The essential conditions for a smooth gel developing in either case were sufficient casein, a quiescent environment, moderate temperature, and sufficient time for reaction.

FACTORS AFFECTING CHYMOSIN ACTION IN MILK

Rennet coagulation in milk is influenced by many factors that ultimately have an impact on cheese characteristics (Kosikowski and Mistry 1997). The cheese maker is usually able to properly control these factors, some of which have a direct affect on the primary phase and others on the secondary.

CHYMOSIN CONCENTRATION

Chymosin concentration affects gel firmness (Lomholt and Qvist 1999), and enzyme kinetics have been used to study these effects. An increase in the chymosin concentration (larger amounts of rennet added to milk) reduces the total time required for rennet clotting, measured by the appearance of the first curd particle. As a result, the secondary phase of rennet action will also proceed much earlier, with the net result of an increase in the rate of increase in gel firmness. This property of chymosin is sometimes used to control the rennet coagulation in concentrated milks, which have a tendency to form firmer curd because of the higher protein content. Lowering the amount of rennet reduces the rate of curd firming. It should also be noted that with an alteration in the amount of rennet added to milk, there also will be a change in the amount of residual chymosin in the cheese.

TEMPERATURE

The optimal condition for curd formation in milk with chymosin is 40–45°C, but this temperature is not suitable for cheese making. Rennet coagulation for cheese making generally occurs at 30–35°C for proper firmness. At lower temperatures, rennet clotting rate is significantly reduced, and at refrigeration temperatures, virtually no curd is obtained.

pH

Chymosin action in milk is optimal at approximately pH 6. This is obtained with starter bacteria. If the pH is lowered further, rennet clotting occurs at a faster rate, and curd firmness is reduced. Lowering pH also changes the water-holding capacity, which will have an impact on curd firmness.

CALCIUM

Calcium has a significant impact on rennet curd, though it does not have a direct effect on the primary phase of rennet action. Addition of ionic calcium, as in the form of calcium chloride, for example, reduces the rate of rennet clot formation time and also increases rennet curd firmness. Similarly, if the calcium content of milk is lowered by approximately 30%, coagulation does not occur. Milks that have a tendency to form weak curd may be fortified with calcium chloride prior to the addition of rennet.

MILK PROCESSING

Heating milk to temperatures higher than approximately 70°C leads to delayed curd formation and weak rennet curd (Vasbinder et al. 2003). In extreme cases, there may be no curd at all. These effects are a result of the formation of a complex involving disulphide linkages between kappa-casein and beta-lactoglobulin under high heat treatment. Under these conditions, the 105-106 bond in kappa-casein is inaccessible for chymosin action. This effect is generally not reversible. Under mild overheating conditions, the addition of 0.02% calcium chloride may help obtain firm rennet curd. Maubois et al. have developed a process for reversing this effect by the use of ultrafiltration. Increasing the protein content by ultrafiltration before or after UHT treatment restores curd-forming ability (Maubois et al. 1972). According to Ferron-Baumy et al. (1991), such a phenomenon results from lowering the zeta potential of casein micelles on ultrafiltration.

Homogenization has a distinct impact on milk rennet coagulation properties. Homogenized milk produces softer curd, but when only the cream portion of milk is homogenized, rennet curd becomes firmer (Nair et al. 2000). This is possibly because of the reduction of fat globule size due to homogenization and coating of the fat globule surface with casein. These particles then act as casein micelles.

Concentrating milk prior to cheese making is now a common practice. Techniques include evaporative concentration, ultrafiltration, and microfiltration. Each of these procedures increases the casein concentration in milk; thus, the rate of casein aggregation during the secondary phase increases. Rennet coagulation usually occurs at a lower degree of kappa-casein hydrolysis, and rennet curd is generally firmer. For example, in unconcentrated milk, approximately 90% kappa-casein must be hydrolyzed by chymosin before curd formation, but in ultrafiltered milk only 50% must be hydrolyzed. (Dalgleish 1992). Under high concentration conditions, rennet curd is extremely firm, and difficulties are encountered in cutting curd using traditional equipment. In cheeses manufactured from highly concentrated milks, rennet should be properly mixed in the milk mixture to prevent localization of rennet action.

GENETIC VARIANTS

Protein polymorphism (genetic variants) of kappa-casein has been demonstrated to have an effect on rennet coagulation (Marzialli and Ng-Kwai-Hang 1986). Protein polymorphism refers to a small variation in the makeup of proteins due to minor differences in the amino acid sequence. Examples include kappa-casein AA, AB, or BB, beta-lactoglobulin AA, AB, and so on. Milk with kappa-casein BB variants forms a firmer rennet curd because of increased casein content associated with this variant of kappa-casein. Some breeds of cows, Jerseys in particular, have larger proportions of this variant. The BB variant of beta-lactoglobulin is also associated with higher casein content in milk.

EFFECT OF CHYMOSIN ON PROTEOLYSIS IN CHEESE

Once rennet curd has been formed and a fresh block of cheese has been obtained, the ripening process begins. During ripening, numerous biochemical reactions occur and lead to unique flavor and texture development. During this process, residual chymosin that is retained in the cheese makes important contributions to the ripening process (Kosikowski and Mistry 1997, Sousa et al. 2001). As the cheese takes form, chymosin hydrolyzes the paracaseins into peptides optimally at pH 5.6 and creates a peptide pool for developing flavor complexes (Kosikowski and Mistry 1997).

The amount of rennet required to coagulate milk within 30 minutes can be considerably below that required to properly break down the paracaseins during cheese ripening. Consequently, using too little rennet in cheese making retards ripening, as discerned by the appearance of the cheese and its end products. A lively, almost translucent looking cheese, after ripening several months, indicates adequate rennet; an opaque, dull-looking cheese indicates inadequate amounts. Apparently, conversion to peptides and later hydrolysis to smaller molecules by bacterial enzymes give the translucent quality. Residual rennet in cheese hydrolyzes alpha-s-1-casein to alpha-s-1-I-casein, which leads to a desirable soft texture in the aged cheese (Lawrence et al. 1987).

Electrophoretic techniques (Ledford et al. 1966) have demonstrated that in most ripening Cheddar cheese from milk coagulated by rennet, *para*-beta-casein largely remains intact while *para*-alpha-casein is highly degraded. According to Fox et al. (1993), if there is too much moisture in cheese or too little salt, the residual chymosin will produce bitter peptides due to excessive proteolysis. In cheeses with high levels of beta-lactoglobulin, as in cheeses made by ultrafiltration, proteolysis by residual chymosin is retarded because of partial inhibition of chymosin by the whey protein (Kosikowski and Mistry 1997).

Edwards (1969) found that milk-coagulating enzymes from the mucors hydrolyze the paracaseins somewhat similarly to rennet, while enzymes from *Cr. parasitica* and the papaya plant completely hydrolyze para-alpha- and para-beta-caseins during ripening.

Proteolytic activity of rennet substitutes, especially microbial and fungal substitutes, is greater than that of chymosin. Cheese yield losses, though small, do occur with these rennets. Barbano and Rasmussen (1992) reported that fat and protein losses to whey were higher with *Rh. miehei* and *Rh. pusillus* compared with those for fermentation-derived chymosin. As a result, the cheese yield efficiency was higher with the latter than with the former two microbial rennets.

EFFECT OF CHYMOSIN ON CHEESE TEXTURE

The formation of a rennet curd is the beginning of the formation of a cheese mass. Thus, a ripened cheese assumes its initial biological identity in the vat or press. This is where practically all of the critical components are assembled and the young cheese becomes ready for further development.

Undisturbed fresh rennet curd is not cheese because it still holds considerable amounts of water and soluble constituents that must be removed before any resemblance to a cheese occurs. This block of curd is cut into thousands of small cubes. Traditionally, this is done with wire knives (Fig. 11.2) but in large automated vats, built-in blades rotate in one direction at a selected speed to systematically cut the curd. Then, the whey, carrying with it lactose, whey proteins, and soluble salts, streams from the cut pores, accelerated by gentle agitation, slowly increasing temperature, and a rising rate of lactic acid production. These factors are manipulated to the degree desired by the cheese maker. Eventually, the free whey is separated from curd.

Figure 11.2. Cutting of rennet curd.

Optimum acid development is essential for forming rennet curd and creating the desired cheese mass. This requires viable, active microbial starters to be added to milk before the addition of rennet. These bacteria should survive the cheese making process.

Beta-D-galactosidase (lactase) and phosphorylating enzymes of the starter bacteria hydrolyze lactose and initiate the glucose-phosphate energy cycles for the ultimate production of lactic acid through various intermediary compounds. Lactose is hydrolyzed to glucose and galactose. Simultaneously, the galactose is converted in the milk to glucose, from which point lactic acid is produced by a rather involved glycolytic pathway. In most cheese milks, the conversion of glucose to lactic acid is conducted homofermentatively by lactic acid bacteria, and the conversions provide energy for the bacteria. For each major cheese type, lactic acid must develop at the correct time, usually not too rapidly, nor too slowly, and in a specific concentration.

The cheese mass, which evolves as the whey drains and the curds coalesce, contains the insoluble salts, $CaHPO_4$ and $MgHPO_4$, which serve as buffers in the pressed cheese mass, and should the acid increase too rapidly during cooking, they will dissolve in the whey. In the drained curds or pressed cheese mass under these circumstances, since no significant pool of insoluble divalent salt remains for conversion into buffering salts, the pH will lower to 4.7–4.8 from an optimum 5.2, leading to a sour acid-ripened cheese. Thus, conservation of a reserve pool of insoluble salts is necessary until the cheese mass is pressed. Thereafter, the insoluble salts are changed into captive soluble salts by the lactic acid and provide the necessary buffering power to maintain optimum pH at a level that keeps the cheese sweet. Such retention also is aided or controlled by the skills of the cheese maker. For Cheddar, excess wetness of the curd before pressing or too rapid an acid development in the whey causes sour cheese. For a Swiss or Emmental, the time period for acid

development differs; most of it takes place in the press, but the principles remain the same (Kosikowski and Mistry 1997).

The development of proper acid in a curd mass controls the microbial flora. Sufficient lactic acid produced at optimum rates favors lactic acid bacteria and discriminates against spoilage or food poisoning bacteria such as coliforms, clostridia, and coagulase-positive staphylococci. But its presence does more than that, for it transforms the chemistry of the curd to provide the strong bonding that is necessary for a smooth, integrated cheese mass.

As discussed earlier, chymosin action on milk results in curd mass involving dicalcium paracasein. Dicalcium paracasein is not readily soluble, stretchable, or possessive of a distinguished appearance. However, if sufficient lactic acid is generated, this compound changes. The developing lactic acid solubilizes considerable calcium, creating a new compound, monocalcium paracasein. The change occurs relatively quickly, but there is still a time requirement. For example, a Cheddar cheese curd mass, salted prior to pressing, may show an 8:2 ratio of dicalcium paracasein to monocalcium paracasein; after 24 hours in the press, it is reversed, 2:8. Monocalcium paracasein has interesting properties. It is soluble in warm 5% salt solution, it can be stretched and pulled when warmed, and it has a live, glistening appearance. The buildup of monocalcium paracasein makes a ripened cheese pliable and elastic. Then, as more lactic acid continues to strip off calcium, some of the monocalcium paracasein changes to free paracasein as follows:

Dicalcium paracasein + lactic acid

→ monocalcium paracasein + calcium lactate

Monocalcium paracasein + lactic acid

→ free paracasein + calcium lactate

Free paracasein is readily attacked by many enzymes, contributing to a well-ripened cheese. The curd mass becomes fully integrated upon the uniform addition of sodium chloride, the amount of which varies widely for different cheese types. Salt directly influences flavor and arrests sharply the acid production by lactic acid starter bacteria. Also, salt helps remove excess water from the curd during pressing and lessens the chances for a weak-bodied cheese. Besides controlling the lactic acid fermentation, salt partially solubilizes monocalcium paracasein. Thus, to a natural ripened cheese or to one that is heat processed, salt helps give a smoothness and plasticity of body that is not fully attainable in its absence.

Texture of cheese is affected significantly during ripening, especially during the first 1–2 weeks, according to Lawrence et al. (1987). During this period, the alpha-s-1-casein is hydrolyzed to alpha-s-1-I by residual chymosin, making the body softer and smoother. Further proteolysis during ripening continues to influence texture.

Pectic Enzymes in Tomatoes

Mary S. Kalamaki, Nikolaos G. Stoforos, and Petros S. Taoukis

Abstract: In this chapter, the enzymes that act on the pectic fraction of the tomato cell wall are described. In a brief introduction, the structure of the pectin network in cell walls of higher plants and a methodology for fractionation of pectic substances are presented. Following, the four most significant pectic enzymes, polygalacturonase, pectin methylesterase, β-galactosidase, and pectate lyase are described in terms of the genes that encode them in tomato, their expression profiles during fruit ripening, as well as the structure and activities of the corresponding proteins. Cases of genetic modification of these enzymes aiming in increasing cell wall integrity, postharvest shelf life, and the processing characteristics of tomatoes are also presented. Finally, the inactivation kinetics of tomato pectic enzymes by heat and high hydrostatic pressure are discussed.

INTRODUCTION

Pectin is a structurally and functionally diverse group of polysaccharides in the plant cell wall. Apart from its role in cell wall architecture, it functions in signaling, cell-to-cell adhesion, determining wall porosity, pH and ionic content, cell growth and differentiation, plant protection, and it is a major contributor to fruit texture. Pectin disassembly during ripening is associated with the development of soft fruit texture, which in turn determines the textural and rheological characteristics of the processed fruit products. In addition, pectin is used in the food industry as a gelling and stabilizing agent in order to improve food rheological behavior. Among the most studied pectic polysaccharides are those of tomato fruit. In this chapter, the enzymes that act on the pectin fraction of tomato cell walls are presented. In the introduction, background information on the structure of pectin in cell walls of higher plants as well as a method used for biochemical analysis of pectic substances are given. Next, pectic enzymes in tomato in terms of genes that encode pectin modifying enzymes, their expression profiles during fruit ripening, and the activities of the respective proteins are discussed. Furthermore, attempts to alter the expression of these enzymes using genetic engineering in order to retard fruit deterioration at the later stages of ripening, increase fruit firmness and shelf life, and improve processing characteristics of tomato products are described. Finally, the inactivation kinetics (by heat and high hydrostatic pressure) of two pectic enzymes, polygalactronase and pectin methylesterase, are discussed.

STRUCTURE OF PECTIN NETWORK IN CELL WALLS OF HIGHER PLANTS

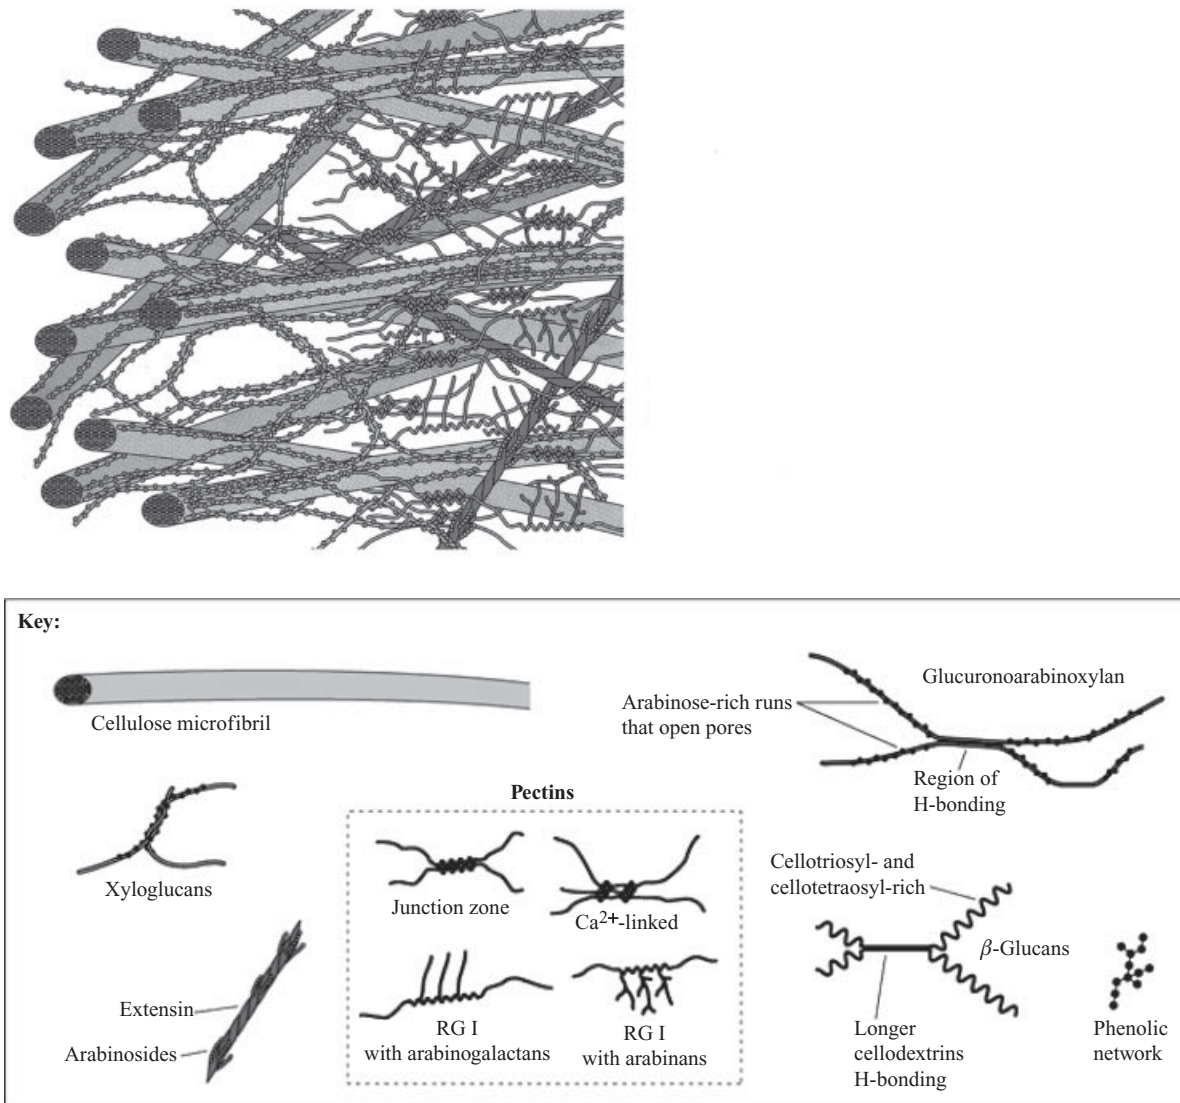
The primary cell wall of higher plants constitutes a complex network, mainly constructed of polysaccharides, structural proteins, and some phenolics. Two co-extensive structural networks can


Figure 12.1. Current structural model of cell walls of flowering plants. (Reprinted from Buchanan et al. 2000).

be identified (Fig. 12.1), the cellulose–matrix glycan network, consisting of cellulose microfibrils held together by matrix glycans (formerly referred to as hemicelluloses), and the pectin network (Carpita and Gibeaut 1993). The way by which these polymers interact with each other is still unclear. Several cell wall models are proposed in an attempt to explain measured physical properties of the wall (Cosgrove 2000, Vincken et al. 2003, Thompson 2005). The cell wall provides shape and structural integrity to the cell, functions as a protective barrier to pathogen invasion and environmental stress, and provides signal molecules important in cell-to-cell signaling, plant–symbiot, and plant–pathogen interactions.

Pectin is an elaborate network of highly hydrated polysaccharides rich in galacturonic acid (GalA). Pectins can be classified in four major groups: homogalacturonan (HGA),

rhamnogalacturonan I (RGI), rhamnogalacturonan II (RGII), and xylogalacturonan (XGA; Mohnen 2008). HGA is a homopolymer of 1,4-α-D-GalA (Fig. 12.2A) usually forming long chains of approximately 100 GalA residues. Galacturonosyl residues are esterified to various extents at the carboxyl group with methanol and may be acetylated at O-2 or O-3. Non-esterified regions of HGA chains can be associated with each other by ionic interactions via calcium ion bridges, forming egg-box-like structures (Fig. 12.2A). At least ten contiguous unesterified galacturonyl residues are required in order to form a stable cross link between HGA chains (Liners et al. 1992). RGI is composed of repeating disaccharide units of 1,2-α-D-rhamnose–1,4-α-D-GalA. Rhamnosyl residues on the backbone of this polymer can be further substituted with β-D-galactose- and α-L-arabinose-rich side chains (Fig. 12.2B). RGII is a minor
Figure 12.2. (**A**) Structure of homogalacturonan showing calcium ion associations. (*Continued*)

constituent of the cell wall (about 10% of pectin) consisting of an HGA backbone that exhibits a complex and highly conserved substitution pattern with many diverse sugars, linked together with more than 20 different linkages. RGII often is found in the wall as dimers cross-linked via borate-diol esters at the apiose residues (Ishii et al. 1999). Another, less-abundant pectic side chain is XGA, which is composed of a galacturonan backbone substituted at *O*-3 with xylosyl side units (Willats et al. 2004). Pectins are covalently interlinked, in part via diferulic acid, and further cross-linked to cellulose, matrix glycans, and other cell wall polymers (Thompson and Fry 2000, Zykwinska et al. 2005, Coenen et al. 2007). The relative abundance and distribution of these polymers in the primary cell wall is not constant. Variation in structure occurs within cell types and plant species, even within the cell wall of a single cell (Knox 2008, Jarvis 2011).

FRACTIONATION OF PECTIC SUBSTANCES

Methods for analyzing cell wall polymeric substances are based on deconstruction of the cell wall by sequentially extracting its components based on solubility. Tomato pericarp is boiled

in ethanol or extracted with tris-buffered phenol to inactivate enzymes (Huber 1992), and cell wall polysaccharides are precipitated with ethanol. Alcohol-insoluble solids are sequentially extracted with 50 mM *trans*-1,2-diaminocyclohexane-*N,N,N′,N′*-tetraacetic acid (CDTA) and 50 mM sodium acetate buffer (pH = 6.5) to obtain the chelator-soluble (ionically bound) pectin. Next, the pellet is extracted with 50 mM sodium carbonate and 20 mM sodium borohydride, which results in breaking of ester bonds, to obtain the carbonate-soluble (covalently bound pectin via ester bonds) pectin. The remaining residue consists primarily of cellulose and matrix glycans with only about 5% remaining pectin. Extracts are dialyzed exhaustively against water at 4°C, and uronic acid (UA) content of dialyzed extracts (extractable polyuronide) is determined using the method of Blumenkrantz and Asboe-Hansen (1973), with GalA as a standard.

BIOCHEMISTRY OF PECTIC ENZYMES IN RIPENING TOMATO FRUIT

Ripening is a genetically coordinated process during which several biochemical and physiological modifications of the fruit
Figure 12.2. (*Continued*) (**B**) Structure of rhamnogalacturonan I. 5-Arabinan (**A**), 4-Galactan (**B**), and Type I Arabinogalactan (**C**) side chains (Reprinted from Buchanan et al. 2000).

occur. These include the conversion of starch to sugars, accumulation of pigments, organic acids, and aroma volatiles, as well as fruit softening. Pectin often consists more than 50% of the fruit cell wall. During ripening, pectin is extensively modified by de novo synthesized enzymes that bring about fruit softening (Brummell 2006, Cantu et al. 2008). The pectin backbone is de-esterified, allowing calcium associations and gelling to occur (Blumer et al. 2000). Pectin is solubilized from the wall complex, followed by a decrease in the average polymer size (Brummell and Labavitch 1997, Chun and Huber 1997). These changes are accompanied by loss of galactosyl and arabinosyl moieties from pectin side chains (Gross 1984). The dissolution of the pectin-rich middle lamella increases cell separation and contributes to softening. Cell wall disassembly in ripening tomato fruit has been extensively studied and a battery of polysaccharide-degrading enzymes involved in this process has been biochemically and genetically characterized (for review, see Brummell and Harpster 2001, Giovannoni 2001, Brummell 2006, Goulao and Oliveira 2008). The most thoroughly studied enzymes that act on the pectic polysaccharides of fruit are polygalacturonase (PG), pectin methylesterase (PME), β-galactosidase (β-GALase), and pectate lyase (PL).

POLYGALACTURONASE

PGs are enzymes that act on the pectin fraction of cell walls and can be divided into endo-PGs and exo-PGs. Exo-PG (EC 3.2.1.67) removes a single GalA residue from the nonreducing end of HGA. Endo-PG (poly(1,4-α-D-galacturonide) glycanohydrolase, EC 3.2.1.15) is responsible for pectin depolymerization by hydrolyzing glycosidic bonds in demethylesterified regions of HGA (Fig. 12.3).

Endo-PGs are encoded by large multigene families with distinct temporal and spatial expression profiles (Hadfield and Bennett 1998). In ripening tomato fruit, the mRNA of one gene is accumulated at high levels, constituting 2% of the total polyadenylated RNA, in a fashion paralleling PG protein accumulation (DellaPenna et al. 1986). PG gene expression during

ripening is ethylene responsive, with very low levels of ethylene (0.15 μL/L) being sufficient to induce PG mRNA accumulation and PG activity (Sitrit and Bennett 1998). PG mRNA levels continue to increase as ripening progresses and persist at the overripe stage. Immunodetectable PG protein accumulation follows the same pattern as mRNA accumulation during ripening and fruit senescence. This mRNA encodes a predicted polypeptide 457 amino acids long containing a signal sequence of 24 amino acids targeting it to the cell's endomembrane system for further processing and secretion. The mature protein is produced by cleaving a 47 amino acids amino-terminal prosequence and a sequence of 13 amino acids from the carboxyl terminus followed by glycosylation. Two isoforms, differing only with respect to the degree of glycosylation, are identified: PG2A, with a molecular mass of 43 kDa, and PG2B with a molecular mass of 46 kDa (Sheehy et al. 1987, DellaPenna and Bennett 1988, Pogson et al. 1991). Another isoform (PG1) accumulates during the early stages of tomato fruit ripening, when PG2 levels are low. PG1 has a molecular mass of 100 kDa and is composed of one or possibly two PG2A or PG2B subunits and the PG β-subunit. Recent work has identified yet another member of the PG1 multiprotein complex; a nonspecific lipid transfer protein of a molecular mass of 8 kDa and no detectable PG activity (Tomassen et al. 2007). When this 8 kDa protein was co-incubated with PG2, an increase in PG2 activity was observed. Moreover, heating of the 8 kDa–PG2 mixture resulted in increased heat stability of the PG2 protein. This report is the first to implicate non-specific lipid transfer proteins in PG-mediated HGA depolymerization in tomato.

The PG β-subunit is an acidic, heavily glycosylated protein. The precursor protein contains a 30 amino acid signal peptide, an N-terminus propeptide of 78 amino acids, the mature protein domain, and a large C-terminus propeptide. The mature protein presents a repeating motif of 14 amino acids and has a size of approximately 37–39 kDa. This difference in size results from different glycosylation patterns or different posttranslational processing at the carboxyl terminus of the protein (Zheng et al. 1992). The PG β-subunit protein is encoded by a single

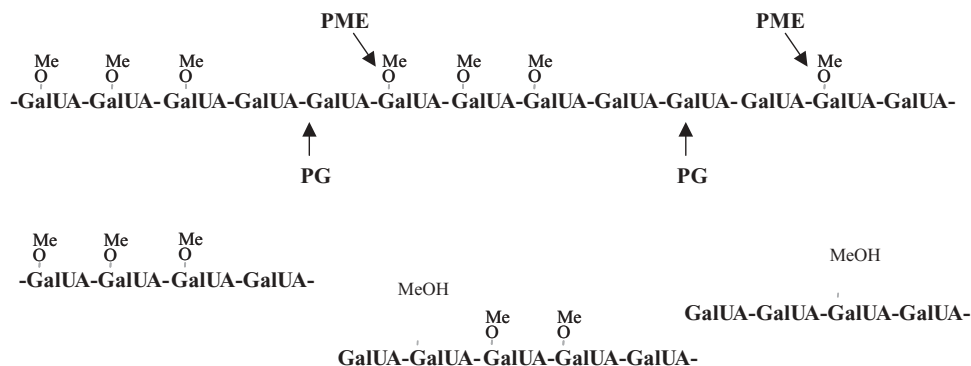

Figure 12.3. Action pattern of PG and PME on pectin backbone. Endo-PG hydrolyzes glycosidic bonds in demethylesterified regions of homogalacturonan. PME catalyzes the removal of methyl ester groups (OMe) from galacturonic acid (GalUA) residues of pectin.

gene. β-subunit mRNA levels increase during fruit development and reach a maximum at 30 days after pollination (i.e., just before the onset of ripening), then decrease to undetectable levels during ripening, whereas immunodetectable β-subunit protein persists throughout fruit development and ripening (Zheng et al. 1992, 1994). The presence of the PG β-subunit alters the physicochemical properties of PG2. Although the PG β-subunit does not possess any glycolytic activity, binding to PG2 leads to modification of PG2 activity with respect to pH optima, heat stability, and Ca^{++} requirements (Knegt et al. 1991, Zheng et al. 1992). Since the β-subunit is localized at the cell wall long before PG2 starts accumulating, it may serve as an anchor to localize PG2 to certain areas of the cell wall (Moore and Bennett 1994, Watson et al. 1994). Another proposed action for the β-subunit is that of limiting access of PG to its substrate or restricting PG activity by binding to the PG protein (Hadfield and Bennett 1998).

Generally, PG-mediated pectin disassembly contributes to fruit softening at the later stages of ripening and during fruit deterioration. Overall, PG activity is neither sufficient nor necessary for fruit softening, as it is evident from data using transgenic tomato lines with suppressed levels of PG mRNA accumulation (discussed later in this chapter) and studies on ripening-impaired tomato mutants. It is evident from data in other fruit, especially melon (Hadfield and Bennett 1998), persimmon (Cutillas-Iturralde et al. 1993), and apple (Wu et al. 1993), that very low levels of PG may be sufficient to catalyze pectin depolymerization in vivo.

PECTIN METHYLESTERASE

PME is a de-esterifying enzyme (EC 3.1.1.11) catalyzing the removal of methyl ester groups from GalA residues of pectin, thus leaving negatively charged carboxylic residues on the pectin backbone (Fig. 12.3). Demethylesterification of galacturonan residues leads to a change in the pH and charge density on the HGA backbone. Free carboxyl groups from adjacent polygalacturonan chains can then associate with calcium or other divalent ions to form gels (Fig. 12.2A). PMEs are encoded by large multigene families in many plant species (Pelloux et al. 2007). In tomato, PME protein is encoded by at least four genes (Turner et al. 1996, Gaffe et al. 1997). The PME polypeptide is 540–580 amino acids long and contains a signal sequence targeting it to the apoplast. The mature protein has a molecular mass of 34–37 kDa and is produced by cleaving an amino-terminal prosequence of approximately 22 kDa (Gaffe et al. 1997). PME is found in multiple isoforms in fruit and other plant tissues (Gaffe et al. 1994). PME isoforms have pIs in the range of 8–8.5 in fruit and around 9.0 in vegetative tissues (Gaffe et al. 1994). Tomato fruit PME is active throughout fruit development and influences accessibility of PG to its substrate. PME transcript accumulates early in tomato fruit development and peaks at the mature green fruit stage, followed by a decline in transcript levels. In contrast, PME protein levels increase in developing fruit at the early stages of ripening and then decline (Harriman et al. 1991, Tieman et al. 1992). Pectin is synthesized in highly methylated form, which is then demethylated by the action of PME. In ripening tomato fruit, the methylester content of pectin

is reduced from an initial 90% at the mature green stage to about 35% in red ripe fruit (Koch and Nevins 1989). Evidence supports the hypothesis that demethylesterification of pectin, which allows Ca^{++} cross-linking to occur, may restrict cell expansion. Constitutive expression of a petunia PME gene in potato resulted in diminished PME activity in some plants. A decrease in PME activity in young stems of these transgenic potato plants correlated with an increased growth rate (Pilling et al. 2000). The action of PME is required for PG action on the pectin backbone (Wakabayashi et al. 2003), indicating a major role of PME in pectin remodeling during ripening.

β-GALACTOSIDASE

β-Galactosidase (EC 3.2.1.23) is an exo-acting enzyme that catalyzes the cleavage of terminal galactose residues from pectin β-(1,4)-D-galactan side chains (Fig. 12.2B). Loss of galactose from wall polysaccharides occurs throughout fruit development, and it accelerates with the onset of ripening (Gross 1984, Seymour et al. 1990). In tomato fruit, β-galactosidase is encoded by a small multigene family of at least seven members, *TBG1* through *7* (Smith et al. 1998, Smith and Gross 2000). On the basis of sequence analysis, it was found that β-galactosidase genes encode putative polypeptides with a predicted molecular mass between 89.8 and 97 kDa except for TBG4, which is predicted to be shorter by 100 amino acids at its carboxyl terminus (Smith and Gross 2000). A signal sequence targeting these proteins to the apoplast was only identified in *TBG4*, *TBG5*, and *TBG6*, whereas *TBG7* is predicted to be targeted to the chloroplast. These seven genes showed distinct expression patterns during fruit ripening, and transcripts of all clones except *TBG2* were detected in other tomato plant tissues (Smith and Gross 2000). β-galactosidase transcripts were also detected in the ripening impaired *ripening-inhibitor* (*rin*), *nonripening* (*nor*), and *never-ripe* (*nr*) mutant tomato lines, which do not soften during ripening; however, the expression profile differed from that in wild-type fruit. *TGB4* mRNA accumulation was impaired in comparison to wild-type levels, whereas accumulation of *TBG6* transcript persisted up to 50 days after pollination in fruit from the three mutant lines (Smith and Gross 2000). Presence of β-galactosidase transcripts in these lines suggests that β-galactosidase activity alone cannot lead to fruit softening. Expression of the *TBG4* clone, which encodes the β-galactosidase isoform II, in yeast resulted in production of active protein. This recombinant protein was able to hydrolyze synthetic substrates (*p*-nitro-phenyl-β-D-galactopyranoside) and lactose, as well as galactose-containing wall polymers (Smith and Gross 2000). Heterologous expression of *TBG1* in yeast also resulted in the production of a protein with exo-galactanase/β-galactosidase activity, also active in cell wall substrates (Carey et al. 2001).

PECTATE LYASE

PLs (pectate transeliminase, EC 4.2.2.2) are a family of enzymes that catalyze the random cleavage of demethylesterified polygalacturonate by β-elimination generating oligomers with 4,5-unsaturated reducing ends (Yoder et al. 1993). PLs were thought

to be of microbial origin and were commonly isolated from macerated plant tissue infected with fungal or bacterial pathogens (Yoder et al. 1993, Barras et al. 1994, Mayans et al. 1997, Yadav et al. 2009). In plants, presence of PL-like sequences was first identified in mature tomato flowers, anthers, and pollen (Wing et al. 1989). Presence of PL in pollen of other species (Albani et al. 1991, Taniguchi et al. 1995, Wu et al. 1996, Kulikauskas and McCormick 1997) as well as in other tissues (Domingo et al. 1998, Milioni et al. 2001, Pilatzke-Wunderlich and Nessler 2001) has been well documented. Recently, PL-like sequences were identified in ripening banana (Pua et al. 2001, Marín-Rodríguez et al. 2003) and strawberry fruit (Medina-Escobar et al. 1997, Benítez-Burraco et al. 2003). Transgenic strawberry plants that expressed a pectin lyase antisense construct were firmer than controls, with the level of PL suppression being correlated to internal fruit firmness (Jiménez-Bermúdez et al. 2002). Additional studies using transgenic strawberries suppressed in the expression of PL support a key role of this enzyme in strawberry fruit softening (Santiago-Doménech et al. 2008, Youssef et al. 2009) and strawberry juice viscosity (Sesmero et al. 2009). PL activity has been detected in ripening cherry tomato fruit grown under different environmental conditions (Rosales et al. 2009) and several putative PL sequences exist in the tomato expressed sequence tag databases (Marín-Rodríguez et al. 2002), suggesting that these enzymes may also contribute to cell wall disassembly during tomato fruit ripening.

GENETIC ENGINEERING OF PECTIC ENZYMES IN TOMATO

Cell wall disassembly in ripening fruit is an important contributor to the texture of fresh fruit. Modification of cell wall enzymatic activity during ripening, using genetic engineering, can impact cell wall polysaccharide metabolism, which in turn can influence texture. Texture of fresh fruit, in turn, influences processing characteristics and final viscosity of processed tomato products. The development of transgenic tomato lines in which the expression of single or multiple genes is altered has allowed the role of specific enzymes to be evaluated both in fresh fruit and processed products.

Single Transgenic Tomato Lines

Polygalacturonase

PG was the first target of genetic modification aiming to retard softening in tomatoes (Sheehy et al. 1988, Smith et al. 1988). Transgenic plants were constructed in which expression of PG was suppressed to 0.5–1% of wild-type levels by the expression of an antisense PG transgene under the control of the cauliflower mosaic virus 35S (CaMV35S) promoter. Fruit with suppressed levels of PG ripened normally as wild-type plants did. An increase in the storage life of the fruit was observed in the PG-suppressed fruit (Schuch et al. 1991, Kramer et al. 1992, Langley et al. 1994). The influence of PG suppression on individual classes of cell wall polymers was investigated (Carrington et al.

1993, Brummell and Labavitch 1997). Sequential extractions of cell wall constituents revealed a decrease in the extent of depolymerization of CDTA soluble polyuronides during fruit ripening. Naturally occurring mutant tomato lines exist, which carry mutations, affecting the normal process of ripening. One of these lines, the *ripening-inhibitor* (*rin*), possesses a single locus mutation that arrests the response to ethylene. *rin* fruit fail to synthesize ethylene and remain green and firm throughout ripening (DellaPenna et al. 1989). Transgenic *rin* plants that expressed a functional PG gene driven by the ethylene-inducible E8 promoter were obtained. After exposure to propylene, PG mRNA accumulation as well as active PG protein was attained, but the fruit did not soften. In these fruit, depolymerization and solubilization of cell wall pectin was at near wild-type levels (Giovannoni et al. 1989, DellaPenna et al. 1990). Altogether, results obtained from analyzing transgenic tomato fruit with altered levels of PG indicate that PG-mediated depolymerization of pectin does not influence softening at the early stages of ripening, and it is not enough to cause fruit softening. However, its outcome is manifested at the later stages of ripening and in fruit senescence.

Suppression of β-subunit expression by the introduction of a β-subunit cDNA in the antisense orientation resulted in reduction of immunodetectable β-subunit protein levels and PG1 protein levels to <1% of PG1 in control fruit. In transgenic lines, PG2 expression remained unaltered (Watson et al. 1994). Suppression of β-subunit expression resulted in increased CDTA-extractible polyuronide levels in transgenic fruit during ripening. The size distribution profiles of CDTA-extractable polyuronides of transgenic and control fruit were nearly identical at the mature green stage. However, at subsequent ripening stages, an increased number of smaller size polyuronides were observed in suppressed β-subunit fruit compared to control fruit (Watson et al. 1994).

Apart from the influence of transgenic modification of PG gene expression on the ripening characteristics and shelf life of fresh tomato fruit, the processing characteristics of these fruit were also modified by the introduction of the PG transgene. A shift in the partitioning of polyuronides in water and CDTA extracts of cell walls from pastes prepared from control and suppressed PG lines was observed. The majority of polyuronides were solubilized in the water extract in control pastes, whereas in pastes from PG-suppressed fruit, a greater proportion was solubilized in CDTA. Water and CDTA extracts from control paste contained a larger amount of smaller sized polyuronides compared with the corresponding extracts from PG-suppressed fruit (Fig. 12.4). However, the molecular size profiles from carbonate-soluble pectin were indistinguishable in the two lines. Tomato paste prepared from PG-suppressed fruit exhibited enhanced gross and serum viscosity (Brummell and Labavitch 1997, Kalamaki 2003). The enhancement of viscosity characteristics of pastes from transgenic PG fruit was attributed to the presence of pectin polymers of higher molecular size and wider size distribution in the serum. Although PG seems to play only a small role in fruit softening, the viscosity of juice and reconstituted paste prepared from antisense PG lines is substantially increased, largely due to reduced break down of soluble
Figure 12.4. Size exclusion chromatography of CDTA-soluble pectin fractions from juice (**A**) and paste (**B**) prepared from control (-) and suppressed PG (.) fruit. Larger polysaccharide molecules elute close to the void volume of the column (fraction 20), whereas small molecules elute at the total column volume (fraction 75). pectin during processing (Schuch et al. 1991, Kramer et al. 1992, Brummell and Labavitch 1997, Kalamaki et al. 2003a).

Pectin Methylesterase

PME protein is accumulated during tomato fruit development, and protein levels increase with the onset of ripening. Production of transgenic tomato lines in which the expression of PME has been suppressed via the introduction of an antisense PME gene driven by the CaMV35S promoter has been reported (Tieman et al. 1992, Hall et al. 1993). PME activity was reduced to less than 10% of wild-type levels, and yet fruit ripened normally. The degree of methylesterification increased significantly in antisense PME fruit by 20–40%, compared to wild-type fruit. Additionally, the amount of chelator-soluble polyuronides decreased in transgenic lines, a result that was expected since demethylesterification is necessary for calcium-mediated cross-linking of pectin. Furthermore, chelator-soluble polyuronides from red ripe tomato pericarp exhibited a larger amount of intermediate size polymers in transgenic lines than controls, indicating a decrease in pectin depolymerization of the chelator-soluble fraction. As described above, PME action precedes that of PG. An increase of about 15% in soluble solids was also observed in transgenic fruit pericarp cell walls (Tieman et al. 1992). Expression of the antisense PME construct also influenced the ability of the fruit tissue to bind divalent cations. Calcium accumulation in the wall was not influenced; however, two-thirds of the total calcium in transgenic fruit was present as soluble calcium, compared to one-third in wild-type fruit (Tieman and Handa 1994). Pectin with a higher degree of methylesterification was found in PME-suppressed fruit, thus presenting fewer sites for calcium binding in the cell wall.

From a food-processing standpoint, the effect of these modifications in PME activity in tomato cell walls during ripening was further investigated. Juice prepared from transgenic antisense PME fruit had about 35–50% higher amount of total UAs than control fruit. Pectin extracted from juice processed either by a hot break, microwave break, or a cold-break method was methylesterified at a higher degree in PME-suppressed juices. In addition, pectin from transgenic fruit was of larger molecular mass compared to controls (Thakur et al. 1996a). Juice and paste prepared from antisense PME fruit had higher viscosity and lower serum separation (Thakur et al. 1996b).

β-Galactosidase

In tomato fruit, a considerable loss of galactose is observed during the course of ripening. This is attributed to the action of enzymes with exo-galactanase/β-galactosidase activity. In order to further investigate their role in ripening, β-galactosidase *TBG1* gene expression was suppressed in transgenic tomato by the expression of a sense construct of 376 bp of the *TBG1* gene driven by the CaMV35S promoter (Carey et al. 2001). Although plants with different expression levels of the transgene were obtained, there was no effect on β-galactosidase protein activity and fruit softening. The results suggest that the *TBG1* gene product may not be readily involved in fruit softening but may act on a specific cell wall substrate (Carey et al. 2001). The β-galactosidase isoform II, encoded by *TBG4*, has been found to accumulate in ripening tomato fruit (Smith et al. 1998). The activity of TBG4, has been suppressed by the expression of an 1.5 kb antisense construct of *TBG4* (Smith et al. 2002). Antisense lines exhibited various degrees of *TBG4* mRNA suppression that was correlated to reduced extractable exo-galactanase activity. In one antisense line, a 40% increase in fruit firmness was observed, which correlated with the highest—among transgenic lines—*TBG4* mRNA suppression, lowest exo-galactanase activity levels, and highest galactosyl content during the early stages of ripening, suggesting a possible role for *TBG4* in the early events of fruit softening. (Smith et al. 2002).

DOUBLE TRANSGENIC TOMATO LINES

As reported above, modifying the expression of individual cell wall hydrolases did not alter fruit softening substantially, suggesting that cell-wall-modifying enzymes may act as a consortium to bring about fruit softening during ripening. Generation of double transgenic lines further aids in understanding the influence of cell wall deconstruction during ripening to the texture of ripe fruit and on the physicochemical properties of processed tomato products.

PG and Expansin

The influence of the suppression of the expression of two cell-wall-related proteins in the same transgenic line has been reported (Kalamaki et al. 2003a, Powell et al. 2003). Tomato lines with simultaneous suppression of the expression of both PG and the ripening-associated expansin have been produced and their chemical and physical properties characterized (Kalamaki et al. 2003a, Powell et al. 2003). Expansins are proteins that lack wall hydrolytic activity and are proposed to act by disrupting the hydrogen bonding between cellulose microfibrils and the cross-linking glycan (xyloglucan) matrix (see Fig. 12.1). Expansins are involved in cell wall disassembly during ripening (Brummell et al. 1999a). Their role in ripening is proposed to be that of loosening the wall and increasing the accessibility of wall polymers to hydrolytic enzymes (Rose and Bennett 1999). In tomato, the product of one expansin gene (*Exp1*) is accumulated exclusively during tomato fruit ripening (Rose et al. 1997, Brummell et al. 1999b). Juices and pastes prepared from fruit with modified levels of *Exp1* exhibit enhanced viscosity attributes (Kalamaki et al. 2003b).

Double transgenic lines were generated by crossing single transgenic homozygous lines. Fruit was harvested at the mature green stage and allowed to ripen at 20°C, and texture was determined as the force required to compress the blossom end of the tomato by 2 mm. Fruit from the double suppressed line were firmer than controls and single transgenic lines at all ripening stages. The same results were observed in fruit ripened on vine. At the red ripe stage, fruit from the double suppressed line were 20% firmer than controls. The flow properties of juice prepared from control, single transgenic, and double transgenic lines at the mature green/breaker, pink, and red ripe stages were evaluated using a Bostwick consistometer. Average juice viscosity decreased as ripening progressed in all genotypes. Juice prepared from fruit of the suppressed PG and the double suppressed line at the red ripe stage exhibited higher viscosity than control (Powell et al. 2003).

In another experiment, an elite processing variety was used as the wild-type background to suppress the expression of PG, Exp1 and both PG and Exp1 in the same line (Kalamaki et al. 2003a). Juice and paste were prepared from control, single suppressed and double suppressed fruit, and their flow properties were characterized. In paste diluted to 5 Brix, an increase in Bostwick consistency of about 18% was observed for the PG-suppressed and the Exp1-suppressed genotypes. Diluted paste from the double suppressed genotype exhibited the highest viscosity; however, this increase in consistency of the double transgenic line was only by an additional 4% compared to the single transgenic lines. Analysis of particle size distributions at 5 Brix in juices and pastes of the different genotypes indicated that suppression of PG or Exp1 results in small increases in the number of particles below a diameter of 250 μm (Fig. 12.5). Suppression of Exp1 also results in the appearance of some larger particles, above 1400 μm in diameter. The presence of these larger fragments shows that suppression of Exp1 affects the way the cells and cell walls rupture during processing. Biochemical characterization of cell wall polymers did not show

Figure 12.5. Particle size determination in juice and paste from control and suppressed PG/Exp1 fruit. (Based on data presented by Kalamaki et al. 2003a.)

large differences in the amounts of extractable polyuronide or neutral sugar in sequential cell wall extracts of juices and diluted concentrates of the various genotypes. Only minor size differences appear in individual polymer sizes in sequential extracts. In suppressed PG genotypes, larger pectin sizes were observed in the CDTA extract. The most dramatic difference was in the carbonate extracts where the double suppressed-line contained larger pectin polymers in all paste concentration levels relative to other genotypes (Kalamaki 2003). Concurrent suppression of PG and Exp1 in the same transgenic line showed an overall increase in viscosity compared to control, but only a 4% additional increase compared with the single transgenic lines. Particle size distribution in juices and pastes from the double transgenic line are more poly-disperse (Fig. 12.5), and particles appear to be more rigid. In this line, an increase in the size of

carbonate-soluble pectin polymers was observed. This size increase could suggest differences in the degree of polymer cross-linking in the particles, resulting in altered particle properties. By modifying cell wall metabolism during ripening, the processing qualities of the resulting juices and pastes were influenced. Hence, reducing the activity of these cell wall enzymes may be a route to the selection of improved processing tomato varieties.

PG and PME

The activities of both PG and PME were suppressed in the same line, and juices were evaluated and compared to single transgenics and controls (Errington et al. 1998). Small differences in Bostwick consistency were observed in hot-break juices with the suppressed PG juices having the highest viscosity. In cold-break juices from PG-suppressed fruit, a time-dependent increase in viscosity was observed. Since a similar increase was not observed in the double transgenic line, it was concluded that in order for the increase in viscosity of cold-break juice to occur, both absence of PG and continued action of PME is required. Absence of PG activity will lead to larger size of pectin, whereas continuing demethylesterification of pectin chains by PME will increase calcium associations between pectin chains, leading to gel formation and thus improved viscosity. In conclusion, simultaneous transgenic suppression of PG and PME expression did not result in an additive effect.

TOMATO PROCESSING

The majority of tomatoes are consumed in a processed form, such as juice, paste, pizza and pasta sauce, and various diced or sliced products. Most of the products are concentrated to different degrees and stored in a concentrated form until ready to use. Industrial concentrates are then diluted to reach the desired final product consistency.

Textural properties of tomato fruit are important contributors to the overall quality in both fresh market and processing tomatoes (Barrett et al. 1998). In some processed products, the most important quality attribute is viscosity (Alviar and Reid 1990). It was recognized early that the structure most closely associated with viscosity is the cell wall (Whittenberger and Nutting 1957). Both the concentration and type of cell wall polymers in the serum fraction and the pulp (particle fraction) are important contributors to viscosity. In serum, the amount and size of the soluble cell wall polymers influence serum viscosity (Beresovsky et al. 1995), whereas in pulp, the size distribution, the shape, and the degree of deformability of cell wall fragments influence viscosity (Den Ouden and Van Vliet 1997). Viscosity is influenced partly by factors that dictate the chemical composition and physical structure of the juice such us fruit variety, cultivation conditions, and the ripening stage of the fruit at harvest. However, it is also influenced by processing factors such as break temperature (Xu et al. 1986), finisher screen size (Den Ouden and Van Vliet 1997), mechanical shearing during manufacture, and degree of concentration (Marsh et al. 1978). These processes result in changes in the microstructure of fruit cell wall that are manifested as changes in viscosity (Xu et al. 1986). Since the integrity of cell wall polymers in the juice is imperative, plant pectic enzymes usually have to be inactivated during processing in order to diminish their activity and prevent pectin degradation. Pectin degradation could lead to increased softening in, for example, pickled vegetable production or peach canning, and loss of viscosity in processed tomato products (Crelier et al. 2001). Although several enzymes are reported to act on cell wall polymers, the main depolymerizing enzyme is PG. Therefore, inactivation of PG activity during tomato processing is essential for viscosity retention. However, there are cases where residual activity of other pectic enzymes is desirable, as for example, with PME. Retention of PME activity with concurrent and complete inactivation of PG could lead to products with higher viscosity (Errington et al. 1998, Crelier et al. 2001). Selective inactivation of PG is not possible with conventional heat treatment, since PME is rather easily inactivated by heat at ambient pressure, while PG requires much more severe heat treatment for complete inactivation. PME is inactivated by heating at 82.2°C for 15 seconds at ambient pressure, while for PG inactivation, a temperature of 104.4°C for 15 seconds is required in canned tomato pulp (Luh and Daoud 1971). In order to achieve this selective inactivation, a combination of heating and high hydrostatic pressure can be used during processing or alternatively, the expression of a particular enzyme can be suppressed using genetic engineering in fruit.

THERMAL INACTIVATION

Thermal processing (that is, exposure of the food to elevated temperatures for relatively short times) has been used for almost 200 years to produce shelf-stable products by inactivating microbial cells, spores, and enzymes in a precisely defined and controlled procedure. Kinetic description of the destructive effects of heat on both desirable and undesirable attributes is essential for proper thermal process design.

At constant temperature and pressure conditions, PME thermal inactivation follows first-order kinetics (Crelier et al. 2001, Fachin et al. 2002, Stoforos et al. 2002).

$$-\frac{dA}{dt} = kA, \quad k = f(T, P, \ldots) \tag{1}$$

where A is the enzyme activity at time t, k the reaction rate constant, and P and T the pressure and temperature process conditions.

Ignoring the pressure dependence, Equation 1 leads to

$$A = A_o e^{-k_T t} \tag{2}$$

where A_o is the initial enzyme activity and the reaction rate constant k_T, function of temperature, is adequately described by Arrhenius kinetics through Equation 3.

$$k_T = k_{T_{ref}} \exp\left[-\frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \tag{3}$$

where $k_{T_{ref}}$ is the reaction rate constant at a constant reference temperature T_{ref}, E_a is the activation energy, and R is the universal gas constant (8.314 J/(mol · K)).
Figure 12.6. Effect of processing temperature on PG and PME thermal inactivation rates at ambient pressure. (Based on data presented by Crelier et al. 2001.)

Figure 12.7. Schematic representation of the effect of processing pressure on PG and PME inactivation rates during high-pressure treatment (at 60°C).

PG thermal inactivation follows first-order kinetics (Crelier et al. 2001, Fachin et al. 2003) as suggested by Equation 2 above, or a fractional conversion model (Equation 4), which suggests a residual enzyme activity at the end of the treatment.

$$A = A_\infty + (A_o - A_\infty)e^{k_T} \tag{4}$$

where A_∞ is the residual enzyme activity after prolonged heating.

From the data presented by Crelier et al. (2001), the effect of processing temperature on crude tomato juice PG and PME thermal inactivation rates at ambient pressure is illustrated in Figure 12.6. The higher resistance of PG, compared with PME, to thermal inactivation is evident (Fig. 12.6). Furthermore, PG inactivation is less sensitive to temperature changes, compared with PME inactivation (as can be seen by comparing the slopes of the corresponding curves in Fig. 12.6). Values for the activation energies (E_a, see Equation 3) equal to 134.5±15.7 kJ/mol for the case of PG and 350.1±6.0 kJ/mol for the case of PME thermal inactivation have been reported (Crelier et al. 2001). It must be noted that the literature values presented here are restricted to the system used in the particular study and are mainly reported here for illustrative purposes. Thus, for example, the origin and the environment (e.g., pH) of the enzyme can influence the heat resistance (k or D—the decimal reduction time—values) of the enzyme as well as the temperature sensitivity (E_a or z—the temperature difference required for 90% change in D—values) of the enzyme thermal inactivation rates.

HIGH PRESSURE INACTIVATION

High hydrostatic pressure processing of foods (i.e., processing at elevated pressures (up to 1000 MPa) and low to moderate temperatures (usually less than 100°C)) has been introduced as an alternative nonthermal technology that causes inactivation of microorganisms and denaturation of several enzymes with minimal destructive effects on the quality and the organolep-
tic characteristics of the product. The improved product quality attained during high-pressure processing of foods, and the potential for production of a variety of novel foods, in particular, desirable characteristics, have made the high pressure technology attractive (Farr 1990, Knorr 1993).

As far as high pressure enzyme inactivation goes, PG is easily inactivated at moderate pressure and temperatures (Crelier et al. 2001, Shook et al. 2001, Fachin et al. 2003), while PME inactivation at elevated pressures reveals an antagonistic (protective) effect between pressure and temperature (Crelier et al. 2001, Shook et al. 2001, Fachin et al. 2002, Stoforos et al. 2002). Depending on the processing temperature, PME inactivation rate at ambient pressure (0.1 MPa) is high, rapidly decreases as pressure increases, practically vanishes at pressures of 100–500 MPa, and thereafter starts increasing again, as illustrated on Figure 12.7.

High pressure inactivation kinetics for both PG and PME follow first-order kinetics (Crelier et al. 2001, Fachin et al. 2002, Stoforos et al. 2002, 2003). Values for the reaction rate constants, k, for high pressure inactivation of PME and PG as a function of processing temperature, at selected conditions, are given in Table 12.1 (Crelier et al. 2001).

Through the activation volume concept (Johnson and Eyring 1970), the pressure effects on the reaction rate constants can be expressed as:

$$k_p = k_{P_{ref}} \exp\left[-\frac{V_a}{R}\frac{(p - P_{ref})}{T}\right] \tag{5}$$

where $k_{P_{ref}}$ is the reaction rate constant at a constant reference pressure, P_{ref}, and V_a is the activation volume.

Models to describe the combined effect of pressure and temperature on tomato PME or PG inactivation have been presented in the literature (Crelier et al. 2001, Stoforos et al. 2002, Fachin et al. 2003). On the basis of the literature data (Crelier et al. 2001), a schematic representation of high pressure inactivation of tomato PG and PME is presented in Figure 12.7. From data like these, one can see the possibilities of selective inactivation

Table 12.1. First-Order Reaction Rate Constants, k (sec^{-1}), for High Pressure PME and PG Inactivation as a Function of Processing Temperature (Based on Data Presented by Crelier et al. 2001)

| | First-Order Reaction Rate Constants, k (sec^{-1}) | | | | | | | |
| | PME | | | | PG | | | |
P (MPa)	60°C	65°C	70°C	75°C	30°C	40°C	50°C	60°C
0.1	$161 \cdot 10^{-6}$	$872 \cdot 10^{-6}$	$6250 \cdot 10^{-6}$	$3680 \cdot 10^{-6}$				
100	$7.58 \cdot 10^{-6}$	$163 \cdot 10^{-6}$	$883 \cdot 10^{-6}$	$574 \cdot 10^{-6}$				$52.6 \cdot 10^{-6}$
300	$9.70 \cdot 10^{-6}$	$112 \cdot 10^{-6}$	$51.4 \cdot 10^{-6}$	$18.3 \cdot 10^{-6}$				$309 \cdot 10^{-6}$
400				$38.6 \cdot 10^{-6}$	$193 \cdot 10^{-6}$	$351 \cdot 10^{-6}$	$701 \cdot 10^{-6}$	$2510 \cdot 10^{-6}$
500				$103 \cdot 10^{-6}$	$3890 \cdot 10^{-6}$	$4090 \cdot 10^{-6}$	$3620 \cdot 10^{-6}$	$7020 \cdot 10^{-6}$
600	$43.8 \cdot 10^{-6}$	$44.3 \cdot 10^{-6}$	$70.2 \cdot 10^{-6}$	$52.5 \cdot 10^{-6}$		$1720 \cdot 10^{-6}$	$4810 \cdot 10^{-6}$	$7530 \cdot 10^{-6}$
800	$1500 \cdot 10^{-6}$	$2330 \cdot 10^{-6}$	$2920 \cdot 10^{-6}$	$2710 \cdot 10^{-6}$				

of the one or the other enzyme by appropriately optimizing the processing conditions (pressure, temperature, and time).

of products with desirable characteristics, by introducing pressure as an additional (to time and temperature) processing variable.

FUTURE PERSPECTIVES

Texture in ripe tomato fruit is largely dictated by cell wall disassembly during the ripening process. Cell wall polysaccharides are depolymerized, and their composition is changed as ripening progresses. The coordinated and synergistic activities of many proteins are responsible for fruit softening, and although expansins and PGs are among the more abundantly expressed proteins in ripening tomato fruit, the modification of their expression has not been sufficient to account for all of the cell wall changes associated with softening or for the overall extent of fruit softening. The texture of fresh fruit directly influences the rheological characteristics of processed tomato products. Viscosity is influenced by modifications of the cell wall architecture but also by changes that may affect polysaccharide mobility and interactions of different components in juices and pastes. Since cell wall metabolism in ripening fruit is a complex process and many enzymes have been identified, which contribute to this process, further insight to the effect of these enzymes on fruit texture and processing attributes can be gained by the simultaneous suppression or over-expression of combinations of enzymes. Of course, the quest is on for identification of enzymes acting on RGI, RGII, and XGA of plant pectins similar to those found in fungi and bacteria (Wong 2008). Moreover, as our knowledge on cell wall biosynthesis and deconstruction increases, the ability to genetically engineer pectin structure in target plants would further improve fruit texture and processing characteristics (Ramakrishna et al. 2003, Vicente et al. 2007, Matas et al. 2009). Manipulation of the expression of multiple ripening-associated genes and/or transcription factors that regulate ripening (Vrebalov et al. 2009) in transgenic tomato lines will further shed light to the ripening physiology, postharvest shelf life and processing qualities of tomato fruit. Finally, the interest exists and efforts are made to design optimal processes for selective enzyme inactivation and thus for production

Seafood Enzymes

M. K. Nielsen and H. H. Nielsen

INTRODUCTION

"Freshness" serves as a basic parameter of quality to a greater extent in seafood than in muscle foods of other types. The attention directed at the freshness of seafood and seafood products is appropriate since certain changes in seafood occur soon after capture and slaughter, often leading to an initial loss in prime quality. Such changes are not necessarily related to microbial spoilage, but may be due to the activity of endogenous enzymes. However, not all postmortem endogenous enzyme activities in seafood lead to a loss in quality; many autolytic changes are important for obtaining the desired texture and taste.

Despite the biological differences between aquatic and terrestrial animals, the biochemical reactions of most animals are identical and are catalyzed by homologous enzymes; only few reactions are unique for certain species. Few reactions are catalyzed by analog enzymes that differ in structure and evolutionary origin. The aquatic habitat can be extreme in various respects including temperature, hydrostatic pressure, and osmotic pressure, compared with the environment of terrestrial animals. These all conditions have thermodynamic implications and can affect the kinetics and stability of marine enzymes. Also, because of the large biological diversity of marine animals and such seasonally determined factors as spawning and the availability of food, seafood species can differ markedly in enzyme activity.

Seafood is a gastronomic term that in principle includes all edible aquatic organisms. In this chapter, it is mainly the "classical" seafood groups—fish, shellfish, and molluscs—that are dealt with. Muscle enzymes are mostly considered, since muscle is the organ of which most seafood products primarily consist. Various other types of seafood enzymes, such as those used in

digestion, are only dealt with to a lesser extent. Further information on seafood enzymes can be found in the book *Seafood Enzymes*, edited by Haard and Simpson (2000), and the references therein.

COLD ADAPTATION OF ENZYMES

Most seafood species are poikilotherm and are thus forced to adapt to the temperature of their habitat, which may range from the freezing point of oceanic seawater, of approximately $-1.9°C$, to temperatures similar to those of the warm-blooded species. Since most of the aquatic environment has a temperature of below $5°C$, the enzyme systems of seafood species are often adapted to low temperatures. Although all enzyme reaction rates are positively correlated with temperature, the enzyme systems of most cold-adapted species exhibit, at low temperatures, catalytic activities similar to those that homologous mesophilic enzymes of warm-blooded animals exhibit at higher in vivo temperatures. This is primarily due to the higher turnover number (k_{cat}) of the cold-adapted enzymes; substrate affinity, estimated by the Michaelis-Menten constant (K_M), and other regulatory mechanisms are generally conserved (Somero 2003).

Several studies reviewed by Simpson and Haard (1987) have found the level of activity of cold-adapted marine enzymes to be higher than that of homologous bovine enzymes; they have also shown marine enzymes to be much lower in thermal stability. Although the attempt has been made to explain the temperature adaptation of the enzymes of marine species in terms of molecular flexibility in a general sense, studies of the molecular structure of such enzymes have not revealed any common structural features that can provide a universal explanation of temperature adaptation. Rather, there appear to be various minor structural adjustments of varying character that provide the necessary flexibility of the protein structure for achieving cold adaption (Smalås et al. 2000, Fields 2001, de Backer et al. 2002).

Since the habitat temperature of most marine animals used as seafood tends to be near to the typical cold storage temperature of approximately $0–5°C$, the enzymatic reaction rates are not thermally depressed at storage temperatures as they usually would be in the meat of warm-blooded animals. With a habitat temperature of seafood of about $5°C$ and Q_{10} values in the normal range of 1.5–2.0, the enzyme reactions during ice storage can thus be expected to proceed at rates four to nine times as high as in warm-blooded animals under similar conditions.

EFFECTS OF PRESSURE ON ENZYME REACTIONS

Although the oceans, with their extreme depth, represent the largest habitat on earth, it is often forgotten that hydrostatic pressure is an important biological variable, affecting the equilibrium constants of all reactions involving changes in volume. Regarding enzyme reactions, pressure affects the molecular stability of enzymes and the intermolecular interactions between enzymes and substrates, cofactors, and macromolecules. Therefore, pressure alterations may change both the concentration of catalytically active enzymes and their kinetic parameters, such as the Michaelis-Menten constant, K_M.

Siebenaller and Somero (1978) showed that the apparent K_M values of a lactate dehydrogenase (LDH) enzyme from a deep-sea fish species are less sensitive to pressure changes than its homologous enzyme from a closely related fish species living in shallow water. Similar relations between the pressure sensitivity of LDH and habitat pressure have been found for the LDH of other marine species (Siebenaller and Somero 1979, Dahlhoff and Somero 1991). In this case, only the LDH substrate interaction was found to be affected by pressure, whereas the turnover number appeared to be unaffected by pressure.

Very high pressures, of 10^8 Pa (ca. 1000 bar), corresponding to the pressure in the deepest trenches on earth can lead to denaturization of proteins. Some deep-sea fish have been found to accumulate particularly high levels of trimethylamine-N-oxide (TMAO). TMAO stabilizes most protein structures and may counteract the effect of pressure on proteins. Adaptation to high pressure thus seems to be achieved both by evolution of pressure-resistant proteins and by adjustments of the intracellular environment.

The metabolic rates of deep-sea fish tend to be lower than those of related species living in shallow waters. Several lines of evidence suggest that the decrease in metabolic rate with increasing depth is largely due to the food consumption levels being lower and to a reduced need for locomotor capability in the darkness (Childress 1995, Gibbs 1997). The latter makes intuitive sense if one considers the often far from streamlined, and sometimes bizarre, anatomy of deep-sea fish species.

OSMOTIC ADAPTATION OF ENZYMES

Marine teleosts (bonefish) are hypoosmotic, having intracellular solute concentrations that are similar to those of terrestrial vertebrates. By contrast, elasmobranches (sharks and rays) are isoosmotic, employing the organic compounds urea and TMAO as osmolytes. Although the concentration of osmolytes can be high, the stability and functionality of enzymes remain mostly unaffected due to the compatibility and balanced counteracting effects of the osmolytes (Yancey et al. 1982).

ENZYMATIC REACTIONS IN THE ENERGY METABOLISM OF SEAFOOD

Most key metabolic pathways such as the glycolysis are found in all animal species, and the majority of animal enzymes are thus homologous. Nevertheless, the energy metabolism of seafood species shows a number of differences from that of terrestrial animals, and these differences contribute to the characteristics of seafood products.

The red and white fish muscle cells are anatomically separated into minor portions of red muscle and major portions of white muscle tissues (see Fig. 13.2 in the Section Postmortem Proteolysis in Fresh Fish). The energy metabolism and the histology of the two muscle tissues differ, the anaerobic white muscle having only few mitochondria and blood vessels. When blood circulation stops after death, the primary effect on the white muscle metabolism is therefore not the seizure of oxygen supply but the accumulation of waste products that are no longer removed.

Adenosine-5′-triphosphate (ATP) is the predominant nucleotide in the muscle cells of rested fish and represents a readily available source of metabolic energy. It regulates numerous biochemical processes and continues to do so during postmortem processes. Both the formation and degradation of ATP continue postmortem, the net ATP level being the result of the difference between the rates of the two processes. In the muscle of rested fish, the ATP content averages 7–10 μmol/g tissue (Cappeln et al. 1999, Gill 2000). This concentration is low in comparison with the turnover of ATP, and the ATP pool would thus be quickly depleted if not continuously replenished.

POSTMORTEM GENERATION OF ATP

In anaerobic tissues such as postmortem muscle tissue, ATP can be generated from glycogen by glycolysis. Smaller amounts of ATP may also be generated by other substances, including creatine or arginine phosphate, glucose, and adenosine diphosphate (ADP).

Creatine phosphate provides an energy store that can be converted into ATP by a reversible transfer of a high-energy phosphoryl group to ADP catalyzed by sarcoplasmic creatine kinase Enzyme Commision number (EC 2.7.3.2). The creatine phosphate in fish is usually depleted within hours after death (Chiba et al. 1991). In many invertebrates, including shellfish, creatine phosphate is often substituted by arginine phosphate, and ATP is thus generated by arginine kinase (EC 2.7.3.3) (Ellington 2001, Takeuchi 2004).

Glucose can enter glycolysis after being phosphorylated by hexokinase (EC 2.7.1.1). Although glucose represents an important energy resource in living animals, it is in scarce supply in postmortem muscle tissue due to the lack of blood circulation, and it contributes only little to the postmortem formation of ATP.

ATP is also formed by the enzyme adenylate kinase (EC 2.7.4.3), which catalyzes the transfer of a phosphoryl group between two molecules of ADP, producing ATP and adenosine monophosphate (AMP). As AMP is formed, adenylate kinase parti-cipates also in the degradation of adenine nucleotides, as will be described later.

The glycogen deposits in fish muscle are generally smaller than the glycogen stores in the muscle of rested mammals. Nevertheless, muscle glycogen is normally responsible for most of the postmortem ATP formation in fish. The degradation of glycogen and the glycolytic formation of ATP and lactate proceed by pathways that are similar to those in mammals. Glycogen is degraded by glycogen phosphorylase (EC 2.4.1.1), producing glucose-1-phosphate. The highly regulated glycogen phosphorylase is inhibited by glucose-1-phosphate and glucose and is activated by AMP. Glucose-1-phosphate is subsequently transformed into glucose-6-phosphate by phosphoglucomutase (EC 5.4.2.2). Glucose-6-phosphate is further degraded by the glycolysis, leading to the formation of ATP, pyruvate, and Nicotineamide adenine dinucleotide (NADH). NADH originates from the reduction of NAD$^+$ during glycolysis. In the absence of oxygen, NAD$^+$ is regenerated by LDH (EC 1.1.1.27), as pyruvate is reduced to lactate. The formation of lactate forms a metabolic blind end and causes pH to fall, the final pH level being reached when the formation of lactate has stopped. The postmortem concentration of lactate reflects, by and large, the total degradation of ATP. Since in living fish, however, removal of lactate from the large white muscle often proceeds only slowly, most lactate formed just before death may remain in the muscle postmortem. Thus, the final pH level in the fish is affected only a little by the stress to which the fish was exposed and the struggle it went through during capture (Foegeding et al. 1996).

The accumulation of lactate in fish is limited by the amount of glycogen in the muscle. Since glycogen is present in fish muscle at only low concentrations, the final pH level of the fish meat is high in comparison to that of other types of meat, typically 6.5–6.7. In species that have more muscular glycogen, this substance rarely limits the formation of lactate, which may continue until the catalysis stops for other reasons, at a pH of approximately 5.5–5.6 in beef (Hultin 1984). The final pH depends not only on the lactate concentration, but also on the pH buffer capacity of the tissue. In the neutral and slightly acidic pH range, the buffer capacity of the muscle tissue in most animals, including fish, originates primarily from histidyl amino acid residues and phosphate groups (Somero 1981, Okuma and Abe 1992). Some fish species, in order to decrease muscular acidosis, have evolved particularly high pH buffer capacities. For example, pelagic fish belonging to the tuna family (genus *Thunnus*) possess a very high glycolytic capacity (Storey 1992, and references therein) and also accumulate high concentrations of histidine and anserine (N-(β-alanyl)-N-methylhistidine) (van Waarde 1988, Dickson 1995). Since tuna and a few other fish species can effectively retain metabolic heat, their core temperature at the time of capture may significantly exceed the water temperature. The high muscle temperature of such species expectedly accelerates autolytic processes, including proteolysis, and may, in combination with the lowering of pH, promote protein denaturation (Haard 2002).

Some species of carp, including goldfish, are able to survive for several months without oxygen. The metabolic adaptation this requires includes substituting ethanol for lactate as the major end product of glycolysis. Ethanol has the advantage over lactate that it can be easily excreted by the gills and does not lead to acidosis (Shoubridge and Hochachka 1980). Under anoxic conditions, NAD$^+$ is thus regenerated by muscular alcohol dehydrogenase (EC 1.1.1.1).

POSTMORTEM DEGRADATION OF NUCLEOTIDES

ATP can be metabolized by various ATPases. In muscle tissues, most of the ATPase activity is represented by Ca^{2+}-dependent myosin ATPase (EC 3.6.1.32) that is directly involved in contraction of the myofibrils. Thus, release of Ca^{2+} from its containment in the sarcoplasmic reticulum dramatically increases the rate of ATP breakdown.

The glycogen consumption during and after slaughter is highly dependent on the fishing technique and the slaughtering process employed. In relaxed muscle cells, the sarcoplasmic Ca^{2+} levels are low, but upon activation by the neuromuscular junctions, Ca^{2+} is released from the sarcoplasmic reticulum, activating myosin ATPase. Since the muscular work performed

during capture is often intensive, the muscular glycogen stores may be almost depleted even before slaughtering takes place. The activation of myosin ATPase by spinally mediated reflexes continues after slaughter, but the extent to which it occurs can be reduced by employing rested harvest techniques such as anesthetization (Jerrett and Holland 1998, Robb et al. 2000); by destroying the nervous system by use of appropriate methods such as *iki jime,* where the brain is destroyed by a spike (Lowe 1993), or by use of still other techniques (Chiba et al. 1991, Berg et al. 1997).

ATPases hydrolyze the terminal phosphate ester bond, forming ADP. ADP is subsequently degraded by adenylate kinase, forming AMP. The degradation of ADP is favored by the removal of AMP by AMP deaminase (EC 3.5.4.6), producing inosine monophosphate (IMP) and ammonia (NH_3). AMP deaminase is a key regulator of the intracellular adenine nucleotide pool and as such is a highly regulated enzyme inhibited by inorganic phosphate, IMP and NH_3 and activated by ATP.

It is widely accepted that IMP contributes to the desirable taste of fresh seafood (Fluke 1994, Gill 2000, Haard 2002). IMP is present in small amounts in freshly caught relaxed fish but builds up during the depletion of ATP (Berg et al. 1997). IMP can be hydrolyzed to form inosine, yet the rate of hydrolysis in fish is generally low, following zero-order kinetics, indicating that the IMP-degrading enzymes are fully substrate saturated (Tomioka et al. 1987, Gill 2000, Itoh and Kimura 2002). However, a large species variation in the degradation of IMP has been shown, and thus IMP may persist during storage for several days or

even weeks (Dingle and Hines 1971, Gill 2000, Haard 2002). The formation of inosine is often rate limiting for the overall breakdown of nucleotides and is considered to constitute the last purely autolytic step in the nucleotide catabolism of chilled fish. The formation of inosine usually indicates a decline in the prime quality of seafood (Surette et al. 1988, Gill 2000, Haard 2002). IMP can be hydrolyzed by various enzymes, 5'-nucleotidase (EC.3.1.3.5) being regarded as the most important of these in the case of chilled fish (Gill 2000, Haard 2002). Several forms of 5'-nucleotidase exist, of which a soluble sarcoplasmic form has been documented in fish (Itoh and Kimura 2002).

The degradation of inosine continues via hypoxanthine and its oxidized products xanthine and uric acid. These reactions, all of them related to spoilage, are catalyzed by both endogenous and microbial enzymes, the activity of the latter depending upon the spoilage flora that are present and thus differing much between species and products. Inosine can be degraded by either nucleoside phosphorylase (EC 2.4.2.1) or inosine nucleosidase (EC 3.2.2.2), leading to the formation of different by-products (see Fig. 13.1). The final two-step oxidation of hypoxanthine is catalyzed by one and the same enzymes, xanthine oxidase (EC 1.1.3.22). The oxidation requires a reintroduction of oxygen in the otherwise anaerobic pathway, which often limits the extent of the xanthine oxidase reaction and causes inosine and hypoxanthine to accumulate. Hypoxanthine is an indicator of spoilage and may contribute to bitter taste (Hughes and Jones 1966). The hydrogen peroxide produced by the oxidation of hypoxanthine can be expected to cause oxidation, but the technological

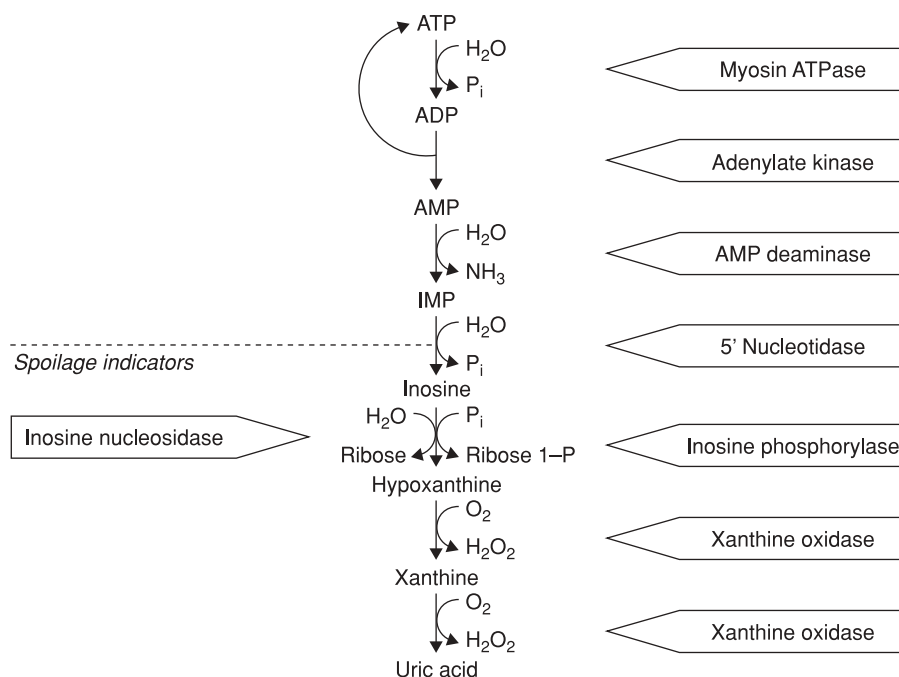

Figure 13.1. The successive reactions of the main pathway for nucleotide degradation in fish. Substances listed below the dotted line are generally considered to be indicators of spoilage. P_i is inorganic phosphate.

implications of this are minor, since it is only after the quality of the fish has declined beyond the level of acceptability that these reactions take place on a large scale.

The relation between the accumulation of breakdown products of ATP and the postmortem storage period of seafood products has resulted in various freshness indicators being defined. Saito et al. (1959) defined a freshness indicator K as a simplified way of expressing the state of nucleotide degradation by a single number:

$$K = 100 \times \frac{[\text{Inosine}] + [\text{Hypoxanthine}]}{\left(\begin{array}{c}[\text{ATP}] + [\text{ADP}] + [\text{AMP}] + [\text{IMP}] \\ + [\text{Inosine}] + [\text{Hypoxanthine}]\end{array}\right)}$$

Higher K values correspond to a lower quality of fish. The K value often increases linearly during the first period of storage on ice, but the K value at sensory rejection differs between species. An alternative and simpler K_i value correlates well with the K value of wild stock fish landed by traditional methods (Karube et al. 1984):

$$K_i = 100 \times \frac{[\text{Inosine}] + [\text{Hypoxanthine}]}{[\text{IMP}] + [\text{Inosine}] + [\text{Hypoxanthine}]}$$

Both K values reflect fish quality well, provided the numerical values involved are not compared directly with the values from other species. Still, K values necessarily remain less descriptive than the concentrations of the degradation products themselves.

ATP is an important regulator of biochemical processes in all animals and continues to be so during the postmortem processes. One of the most striking postmortem changes is that of rigor mortis. When the concentration of ATP is low, the contractile filaments lock into each other and cause the otherwise soft and elastic muscle tissue to stiffen. Rigor mortis is thus a direct consequence of ATP depletion. The biochemical basis and physical aspects of rigor mortis are reviewed by Hultin (1984) and Foegeding et al. (1996).

ATP depletion and the onset of rigor mortis in fish are highly correlated with the residual glycogen content at the time of death and with the rate of ATP depletion. The onset of rigor mortis may occur only a few minutes after death or may be postponed for up to several days when rested harvest techniques, gentle handling, and optimal storage conditions are employed (Azam et al. 1990, Lowe et al. 1993, Skjervold et al. 2001). The strength of rigor mortis is greater when it starts soon after death (Berg et al. 1997). Although the recommended temperature for chilled storage is generally close to 0°C, in some fish from tropical and subtropical waters, the degradation of nucleotides has been found to be slower, and the onset of rigor mortis to be further delayed when the storage temperature is elevated to 5°C, 10°C, and even 20°C (Saito et al. 1959, Iwamoto et al. 1987, 1991).

Rigor mortis impedes filleting and processing of fish. In the traditional fishing industry, therefore, filleting is often postponed until rigor mortis has been resolved. In aquaculture, however, it has been shown that rested harvesting techniques can postpone rigor mortis sufficiently to allow prerigor filleting to be carried out (Skjervold et al. 2001). Fillets from prerigor filleted fish shorten, in accordance with the rigor contraction of the muscle fibers, by as much as 8%. Prerigor filleting has few problems with gaping, since the rigor contraction of the fillet is not hindered by the backbone (Skjervold et al. 2001). Gaping, which represents the formation of fractures between segments of the fillets, is described further in the Section Postmortem Proteolysis in Fresh Fish.

All enzyme reactions are virtually stopped during freezing at low temperatures. The ATP content of frozen prerigor fish can thus be stabilized. During the subsequent thawing of prerigor fish muscle, the leakage of Ca^{2+} from the organelles results in a very high level of myosin Ca^{2+}–ATPase activity and a rapid consumption of ATP. This leads to a strong form of rigor mortis called thaw rigor. Thaw rigor results in an increase in drip loss, in flavor changes, and in a dry and tough texture (Jones 1965) and gaping (Jones 1969). Thaw rigor can be avoided by controlled thawing, holding the frozen products at intermediate freezing temperatures above −20°C for a period of time (Mcdonald and Jones 1976, Cappeln et al. 1999). During this holding period, ATP is degraded at moderate rates, allowing a slow onset of rigor mortis in the partially frozen state.
Rigor mortis is a temporary condition, even though in the absence of ATP, the actin-myosin complex is locked. The resolution of rigor mortis is due to structural decay elsewhere in the muscular structure, as will be discussed later.

ENZYMATIC DEGRADATION OF TRIMETHYLAMINE-*N*-OXIDE

The substance TMAO is found in all marine seafood species but occurs in some freshwater fish as well (Anthoni et al. 1990, Parab and Rao 1984, Niizeki et al. 2002). It contributes to cellular osmotic pressure, as previously described, but several other physiological functions of TMAO have also been suggested. TMAO itself is a harmless and nontoxic constituent, yet it forms a precursor of undesirable breakdown products. In seafood products, TMAO can be degraded enzymatically by two alternative pathways as described later.

THE TRIMETHYLAMINE-*N*-OXIDE REDUCTASE REACTION

Many common spoilage bacteria reduce TMAO to trimethylamine (TMA) by means of the enzyme TMAO reductase (EC 1.6.6.9):

$$O{=}N\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{|}}{-}CH_3 + NADH \rightarrow N\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{|}}{-}CH_3 + NAD^+ + H_2O \;\cdot$$
TMA has a strong fishy odor, and TMAO reductase activity is responsible for the typical off-odor of spoiled fish. Since TMAO reductase is of microbial origin, the formation of TMA occurs primarily under conditions such as cold storage that allow microbial growth to take place. TMA is thus an important spoilage indicator of fresh seafood products. The formation of

TMA is further discussed in the food microbiology literature (e.g., Barrett and Kwan 1985, Dalgaard 2000).

THE TRIMETHYLAMINE-*N*-OXIDE ALDOLASE REACTION

TMAO is also the precursor of the formation of dimethylamine (DMA) and formaldehyde:

$$
\begin{array}{ccc}
\text{CH}_3 & \text{CH}_3 & \quad\quad\ \text{O} \\
| & | & \quad\quad\ \parallel \\
\text{O}{=}\text{N}{-}\text{CH}_3 \rightarrow \text{H}{-}\text{N}{-}\text{CH}_3 + \text{H}{-}\text{C} & \cdot \\
| & | & \quad\ \ \backslash \\
\text{CH}_3 & & \quad\quad\ \text{H}
\end{array}
$$

This reaction is catalyzed by trimethylamine-*N*-oxide aldolase (TMAOase or TMAO demethylase, EC 4.1.2.32) but may also to some extent be nonenzymatic, catalyzed by iron and various reductants (Vaisey 1956, Spinelli and Koury 1981, Nitisewojo and Hultin 1986, Kimura et al. 2002). In most cases in which significant amounts of formaldehyde and DMA are accumulated, however, species possessing TMAOase enzyme activity are involved. The reaction leads to cleavage of a C-N bond and the elimination of an aldehyde, resulting in the classification of TMAOase as a lyase (EC 4.1.2.32) and the International Union of Biochemistry and Molecular Biology name aldolase.

DMA is a reactive secondary amine with a milder odor than TMA. Formaldehyde is highly reactive and strongly affects the texture of fish meat by making it tougher, harder, more fibrous, and less juicy, as well as increasing the drip loss in the thawed products. The quality changes are associated with a loss in protein solubility and in particular the solubility of the myofibrillar proteins. For reviews, see Sikorski and Kostuch (1982), Hultin (1992), Mackie (1993), Sikorski and Kolakowska (1994), and Sotelo et al. (1995).

Formaldehyde can react with a number of chemical groups, including some protein amino acid residues and terminal amino groups, resulting in denaturation and possibly in the cross-linking of proteins, both of which are believed to be the cause of the observed effects on seafood products. The formaldehyde concentration in severely damaged seafood products may reach 240 μg/g (Nielsen and Jørgensen 2004). These concentrations are generally considered nontoxic, but may still exceed various national trade barrier limits.

Whereas TMAO is widespread, TMAOase is only found in a limited number of animals, many of which belong to the order of gadiform fish (pollock, cod, etc.). In gadiform species, the highest levels of enzyme activity are found in the inner organs (kidney, spleen, and intestine), while the enzyme activity in the large white muscle is low. The formation of DMA and formaldehyde in various tissues of certain nongadiform fish, as well as of crustaceans and mollusks, has also been reported, as reviewed by Sotelo and Rehbein (2000), although the taxonomic distribution of the enzyme has not been investigated systematically. The TMAOase content of gadiform fish exhibits large individual variation, probably due to the influence of biological factors that have not yet been adequately studied (Nielsen and Jørgensen 2004).

The enzyme is stable and tolerates both high salt concentrations and freezing. The accumulation of DMA and formaldehyde progresses only slowly, and most of the accumulation is produced during prolonged frozen storage or cold storage of the salted fish (e.g., salted cod and bacalao). During freezing, the enzymatic reaction proceeds as long as liquid water and substrate are available. In practice, the formation of DMA and formaldehyde is found at temperatures down to approximately $-30°$C (Sotelo and Rehbein 2000). At higher temperatures, the rate of formation of formaldehyde is also higher; thus, freezing of gadiform fish at insufficiently low temperatures may result in dramatic changes in the solubility of myofibrillar proteins within a few weeks (Nielsen and Jørgensen 2004).

Despite the TMAOase concentration of the white muscle being low, it is the enzyme activity of the white muscle that is responsible for the accumulation of formaldehyde in whole fish and in fillets (Nielsen and Jørgensen 2004). In the case of minced products, even minor contamination by TMAOase-rich tissues leads to a marked rise in the rate of accumulation (Dingle et al. 1977, Lundstrøm et al. 1982, Rehbein 1988, Rehbein et al. 1997). Despite its dependency upon other factors, such as cofactors, the rate of accumulation of formaldehyde can to a large extent be predicted from the TMAOase enzyme activity of fish meat alone (Nielsen and Jørgensen 2004).

The physiological function of TMAOase remains unknown. The formation of formaldehyde could have a digestive function, yet this would not explain the high TMAOase content of the kidney and spleen. Accordingly, it has been speculated that TMAO may not even be its primary natural substrate (Sotelo and Rehbein 2000).

The in vitro reaction rate is low without the presence of a number of redox-active cofactors. Although the overall TMAOase reaction is not a redox reaction, its dependency on redox agents shows that the reaction mechanism must include redox steps. Little is known about the in vivo regulation of TMAOase, but studies suggest the importance of nucleotide coenzymes and iron (Hultin 1992). TMAOase appears to be membrane bound and is only partly soluble in aqueous solutions. This has complications for its purification and is one of the main reasons why the complete characterization of the enzyme remains yet to be done.

POSTMORTEM PROTEOLYSIS IN FRESH FISH

Postmortem proteolysis is an important factor in many changes in seafood quality. During cold storage, the postmortem proteolysis of myofibrillar and connective tissue proteins contributes to deterioration in texture. Despite the natural tenderness of seafood, texture is an important quality parameter, in fish and shellfish alike. Deterioration in seafood quality through proteolysis involves a softening of the muscle tissue. This reduces the cohesiveness of the muscle segments in fillets, which promotes gaping, a formation of gaps and slits between muscle segments. The negative character of this effect contrasts with the effect of postmortem proteolysis on the meat of cattle and
Figure 13.2. Gross anatomy of fish muscle. (Drawing courtesy of A. S. Matforsk, Norwegian Food Research Institute.)

pigs, in which the degradation of myofibrillar proteins produces a highly desired tenderization in the conversion of muscle to meat.

The proteolytic enzymes that cause a softening of seafood are of basically the same classes as those found in terrestrial animals. The special effects of proteolysis on seafood result from the combined action of the homologous proteolytic enzymes on the characteristic muscle structures of seafood. The muscle of fish differs on a macrostructural level from that of mammals, fish muscle being segmented into muscle blocks called myotomes. A myotome consists of a single layer of muscle fibers arranged side by side and separated from the muscle fibers of the adjacent myotomes by collagenous sheets termed the myocommata (Bremner and Hallett 1985). See Figure 13.2.

A myotome resembles a mammalian skeletal muscle in terms of its intracellular structure (see Fig. 13.3) and the composition of the extracellular matrix. Each muscle fiber is surrounded by fine collagen fibers, the endomysium, joined with a larger network of collagen fibers, the perimysium, which is contiguous with the myocommata (Bremner and Hallet 1985). Although the endomysium, perimysium, and myocommata are considered to be discrete areas of the extracellular matrix, they join to form a single weave.

Such phenomena in seafood as softening, gaping, and the resolution of rigor are believed to be caused by hydrolysis of the myofibrillar and the extracellular matrix proteins. Initially, the disintegration of the attachment between the myocommata and muscle fibers leads to the resolution of rigor (Taylor et al. 2002). Endogenous proteolytic enzymes that cleave muscle proteins under physiological conditions and at neutral pH can be a factor in the resolution of rigor mortis. The continuation of this process is regarded as one of the main causes of gaping (Taylor et al. 2002, Fletcher et al. 1997).

The softening of fish muscle appears to be the result of multiple changes in muscle structure. Histological studies have shown that the attachment between muscle fibers in fish muscle is broken during ice storage and has been associated with a loss of "hardness" as measured by instrumental texture analysis (Taylor et al. 2002). During cold storage, the junction between the myofibrils and connective tissue of the myocommata is hydrolyzed (Bremner 1999, Fletcher et al. 1997, Taylor et al. 2002), and the collagen fibers of the perimysium surrounding the bundles of muscle fibers are degraded (Ando et al. 1995, Sato et al. 2002).

It appears that cleavage of the costameric proteins that link the myofibrils (the sarcomere) with the sarcolemma (the cell membrane), and of the basement membrane, which is attached

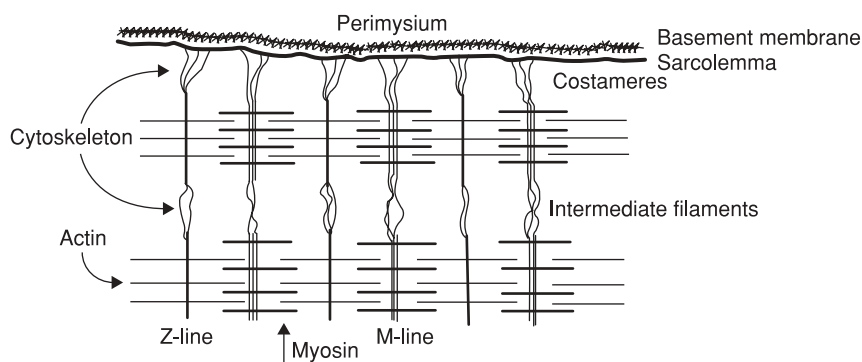

Figure 13.3. A longitudinal view of the intracellular structure of a skeletal muscle fiber showing the contractile elements (actin and myosin), the cytoskeleton, and the attachment to the extracellular matrix (endomysium and perimysium). (Adapted from Lødemel 2004.)

to the fine collagen fibers of the endomysium (see Fig. 13.3), leads to muscle fibers being detached, which results in softening. Studies have shown that the costameric proteins found in fish muscle are already degraded 24 hours postmortem (Papa et al. 1997). This emphasizes the importance of early postmortem changes.

It has been shown that changes in the collagen fraction of the extracellular matrix and the softening of fish are related. Collagen V, a minor constituent of the pericellular connective tissue of fish muscle, becomes soluble when rapid softening takes place, whereas no solubilization is observed in fish that do not soften (Sato et al. 2002). Recent studies also indicate a degradation of the most abundant collagen in fish muscle, collagen I, during 24 hours of cold storage (Shigemura et al. 2004). This indicates that the degradation of collagen and the resulting weakening of the intramuscular pericellular connective tissue also play a role in the textural changes in fish muscle that occur early postmortem.

A number of studies have revealed structural changes in the myofibrillar proteins in fish muscle during cold storage. Analysis of myofibrillar proteins from the muscle of salmon stored at 0°C for as long as 23 days has shown that several new protein fragments form (Lund and Nielsen 2001). Other studies suggest that predominantly proteins of the cytoskeletal network, such as the high molecular weight proteins titin and nebulin, are degraded (Busconi et al. 1989, Astier et al. 1991). The extent of degradation of the muscle myofibrillar proteins varies among species. It has been found, for example, that the intermediate filament protein desmin is clearly degraded during the cold storage of turbot and sardines but that no degradation occurs during the cold storage of sea bass and brown trout (Verrez-Bagnis et al. 1999).

As research shows, both myofibrillar and extracellular matrix proteins in the muscle of many fish are degraded during storage, and textural changes can be expected to result from degradation of proteins from both structures.

PROTEASES IN FISH MUSCLE

The structural and biochemical changes just described can be considered to largely represent the concerted action of different endogenous proteolytic enzymes. Proteolytic enzymes of all major classes have been documented in the muscle of various fish species. An overview of the different proteases believed to play a role in the postmortem proteolysis of seafood is presented later. Further information on the proteases found in fish and marine invertebrates can be found in reviews by Kolodziejska and Sikorski (1995, 1996).

Matrix Metalloproteinases

Matrix metalloproteinases are extracellular enzymes involved in the in vivo catabolism (degradation) of the extracellular matrix (degradation of the helical regions of the collagens). They have been isolated from rainbow trout (Saito et al. 2000), Japanese flounder (Kinoshita et al. 2002) and Pacific rockfish (Bracho and Haard 1995). Collagenolytic and gelatinolytic activities have

also been detected in the muscle of winter flounder (Teruel and Simpson 1995), yellowtail (Kubota et al. 1998), ayu (Kubota et al. 2000), salmon, and cod (Lødemel and Olsen 2003). Type I collagen is solubilized and degraded by matrix metalloproteinases in rainbow trout (Saito et al. 2000), Japanese flounder (Kubota et al. 2003), and Pacific rockfish (Bracho and Haard 1995), suggesting that these proteases can participate in postmortem textural changes.

Cathepsins

Lysosomal proteinases such as cathepsins B, D, and L have been isolated from a number of fish species, including herring (Nielsen and Nielsen 2001), mackerel (Aoki and Ueno 1997), and tilapia (Jiang et al. 1991). In vitro studies show that certain cathepsins are capable of cleaving myofibrillar proteins (Ogata et al. 1998, Nielsen and Nielsen 2001) and may also participate in degradation of the extracellular matrix since they can cleave both nonhelical regions of the collagen (Yamashita and Konagaya 1991) and collagen that has already been partly degraded by matrix metalloproteinases. Since cathepsins in the muscle of living fish are located in the lysosomes, they are not originally in direct contact with either the myofibrils or the extracellular matrix, although it has been shown that the enzymes leak from the lysosomes in fish muscle postmortem, and from lysosomes in bovine muscles postmortem as well (Geromel and Montgomery 1980, Ertbjerg et al. 1999).

Calpains

Calpains have been reported in the muscle of various fish species (Wang and Jiang 1991, Watson et al. 1992). They are only active in the neutral pH range, although research shows that they also remain active at the slightly acidic postmortem pH (Wang and Jiang 1991) and are capable of degrading myofibrillar proteins in vitro (Verrez-Bagnis et al. 2002, Geesink et al. 2000). This suggests a participation in the postmortem hydrolysis of fish muscle. Watson et al. (1992) found evidence for calpains being involved in the degradation of myofibrillar proteins in tuna, leading to the muscle becoming pale and grainy, which is referred to as "burnt tuna."

20S Proteasome

The 20S proteasome enzyme is a 700 kDa multicatalytic proteinase with three major catalytic sites. The term 20S refers to its sedimentation coefficient. In the eukaryotic cells, the enzyme exists in the cytoplasm, either in a free state or associated with large regulatory complexes. In vivo, it is involved in nonlysosomal proteolysis and apoptosis. Research strongly indicates that this proteasome is involved in meat tenderization in cattle (Sentandreu et al. 2002). Although proteasomes have been detected in the muscle of such fish species as carp (Kinoshita et al. 1990a), white croaker (Busconi et al. 1992), and salmon (Stoknes and Rustad 1995), their postmortem activity in fish muscle has not been clarified.

Heat-Stable Alkaline Proteinases

Kinoshita et al. (1990b) reported the existence of up to four distinct heat-stable alkaline proteinase (HAP) in fish muscle: two sarcoplasmic proteinases activated at 50°C and 60°C, and two myofibril-associated proteinases activated at 50°C and 60°C, respectively. The distribution of the four proteinases was found to be quite diverse among the 12 fish species that were studied. The mechanisms activating these proteinases in vivo and their precise physiological functions are not clear.

The participation of one or the other protease in the many different degradation scenarios that occur has still been only partially elucidated. However, various studies have found a close relationship between protein degradation in fish muscle and the activity of specific proteases. A high level of activity of cathepsin L has been found in chum salmon during spawning, a period during which the fish exhibit an extensive softening in texture (Yamashita and Konagaya 1990). Similarly, Kubota et al. (2000) found an increase in gelatinolytic activity in the muscle of ayu during spawning, a period involving a concurrent marked decrease in muscle firmness. Also, in the muscle of hake, a considerably higher level of proteolytic activity during the prespawning period than in the postspawning period was found (Perez-Borla et al. 2002).

The possible existence of a direct link between protease activity and texture has been explored in situ by perfusing protease inhibitors into fish muscle and later measuring changes in texture during cold storage. The activity of metalloproteinase and of trypsin-like serine protease was found in this way to play a role in the softening of flounder (Kubota et al. 2001) and of tilapia (Ishida et al. 2003).

POSTMORTEM HYDROLYSIS OF LIPIDS IN SEAFOOD DURING FROZEN AND COLD STORAGE

Changes in the lipid fraction of fish muscle during storage can lead to changes in quality. Both the content and the composition of the lipids in fish muscle can vary considerably between species and from one time of year to another, and also differ greatly depending upon whether white or red muscle fibers are involved. As already mentioned, these two types of muscle fibers are separated from each other, the white fibers generally constituting most of the muscle as a whole, although fish species vary considerably in the amounts of dark meat, which has a higher myoglobin and lipid content. In species like tuna and in small and fatty pelagic fish, the dark muscle can constitute up to 48% of the muscle as a whole, whereas in lean fish such as cod and flounder, the dark muscle constitutes only a small percentage of the muscle (Love 1970). Since triglycerides are deposited primarily in the dark muscle, providing fatty acids as substrate to aerobic metabolism, whereas the phospholipids represent most of the lipid fraction of the white muscle, phospholipids constitute a major part of the lipid fraction in lean fish (Lopez-Amaya and Marangoni 2000b).

Not much research on lipid hydrolysis in fresh fish during ice storage has been carried out, research having concentrated more on changes in the lipid fraction during frozen storage. This could be due to freezing being the most common way of storing and processing seafood and to lipid hydrolysis playing no appreciable role in ice-stored fish before microbial spoilage becomes extreme. Knudsen (1989), however, detected an increase in free fatty acids in cod muscle during 11 days of ice storage, indicative of the occurrence of lipolytic enzyme activity, an increase that was most pronounced during days 5 to 11. Ohshima et al. (1984) reported a similar delay in the increase in free fatty acids in cod muscle stored in ice for 30 days. Both results are basically consistent with the observation of Geromel and Montgomery (1980) of no lysosomal lipase activity being evident in trout muscle after seven days on ice. In contrast, the authors reported that slow freezing and fluctuations in temperature during frozen storage were found to result in the release of acid lipase from the lysosomes of the dark muscle of rainbow trout.

Several researchers have reported an increase in free fatty acids during frozen storage of muscle of different fish species such as trout (Ingemansson et al. 1995), salmon (Refsgaard et al. 1998, 2000), rayfish (Fernandez-Reiriz et al. 1995), tuna, cod, and prawn (Kaneniwa et al. 2004). The release of free fatty acids during frozen storage can induce changes in texture by stimulation of protein denaturation and through off-flavors being produced by lipid oxidation (Lopez-Amaya and Marangoni 2000b). Refsgaard et al. (1998, 2000) observed a marked increase in free fatty acids in salmon stored at −10°C and −20°C. This increase in free fatty acid content was connected with changes in sensory attributes, suggesting that lipolysis plays a significant role in deterioration of the quality of salmon during frozen storage.

Kaneniwa et al. (2004) detected a large variation in the formation of free fatty acids among nine species of fish and shellfish stored at −10°C for 30 days. Once again, this demonstrates the large variation in enzyme activity in seafood species. Findings of Ben-gigirey et al. (1999) indicate that the temperature at which fish are stored has a clear influence on the lipase activity occurring in the muscle. They noted, for example, that the formation of free fatty acids in the muscle of albacore tuna during storage for the period of a year was considerably higher at −18°C than at −25°C.

Two classes of lipases, the lysosomal lipases and the phospholipases, are apparently involved in the hydrolysis of lipids in fish muscle during storage. Nayak et al. (2003) found significant differences among four fish species (rohu, oil sardine, mullet, and Indian mackerel) in the degree of red muscle lipase activity. This is quite in line with differences in lipid hydrolysis among species that Kaneniwa et al. (2004) reported.

Although both the lipase activity and the formation of free fatty acids in fish muscle are well documented, only a few studies have actually isolated and characterized the muscle lipases and phospholipases involved. Aaen et al. (1995) have isolated and characterized an acidic phospholipase from cod muscle, and Hirano et al. (2000) a phospholipase from the white muscle of bonito. Similarly, triacylglycerol lipase from salmon and from rainbow trout has been isolated and characterized by Sheridan and Allen (1984) and by Michelsen et al. (1994), respectively. Knowledge of the properties of the lipolytic enzymes in the

muscle in seafood and of the responses the enzymes show to various processing parameters, however, is sparse. Extensive reviews of work done on the lipases and phospholipases in seafood has been presented by Lopez-Amaya and Marangoni (2000a,b).

ENDOGENOUS ENZYMATIC REACTIONS DURING THE PROCESSING OF SEAFOOD

During seafood processing such as salting, heating, fermentation, and freezing, endogenous enzymes can be active and contribute to the sensory characteristics of the final product. Such endogenous enzyme activities are sometimes necessary in order to obtain the desired taste and texture.

SALTING OF FISH

Salting has been used in many countries for centuries as a means of preserving fish. Today, the primary purpose of salting fish is no longer only to preserve them. Instead, salting enables fish products with sensory attributes that are sought after, such as salted herring and salted cod, as produced on the northern European continent and in Scandinavia. Enzymatic degradation of muscle proteins during salting is a factor that contributes to the development of the right texture and taste of the products.

Ripening of Salt-Cured Fish

Spiced sugar–salted herring in its traditional form is made by mixing approximately 100 kg of headed, ungutted herring with 15 kg of salt and 7 kg of sugar in barrels, usually adding spices as well. After a day or two, after a blood brine has been formed, saturated brine is added, after which the barrels are stored at 0–5°C for up to a year. During this period, a ripening of the herring takes place, and it achieves its characteristic taste and texture (Stefánsson et al. 1995).

During the ripening period, both intestinal and muscle proteases participate in the degradation of muscle protein, contributing to the characteristic softening of the fillet and liberating free amino acids and small peptides that help create the characteristic flavor of the product (Nielsen 1995, Olsen and Skåra 1997). Studies have shown that intestinal trypsin- and chymotrypsin-like enzymes migrate into the fillet, where they play an active role in the degradation of muscle proteins during storage (Engvang and Nielsen 2000, Stefánsson et al. 2000). Furthermore, Nielsen (1995) shows that muscle amino peptidases are also active in the salted herring during storage.

In southern Europe, a similar product based on the use of whole sardines or anchovies is produced. In contrast to the salted herring from Scandinavia, these salted sardines and anchovies are stored at ambient temperature, which can vary between 18°C and 30°C (Nunes et al. 1997). Nunes et al. (1997) found that proteases from both the intestines and the muscles participated in the ripening of sardines *(Sardina pilchardus)*. Hernadez-Herrero et al. (1999) reported an increase in proteinase activity as well as in protein hydrolysis during the storage of salted anchovies

(Engraulis encrasicolus) and found a close relationship between proteolysis and the development of the sensory characteristics of the product.

PRODUCTION OF FISH SAUCE AND FISH PASTE

Fish sauce and fish paste are fermented fish products produced mainly in Southeast Asia, where they are highly appreciated food flavorings. Fish sauce is the liquefied protein fraction, and fish paste is the "solid" protein fraction obtained from the prolonged hydrolysis of heavily salted small pelagic fish. Production takes place in closed tanks at ambient tropical temperatures during a period of several months (Gildberg 2001, Saishiti 1994). The hydrolysis represents the combined action of the fishes' own digestive proteases and of enzymes from halotolerant lactic acid bacteria (Saishiti 1994). Orejani and Liston (1981) concluded, on the basis of inhibitor studies, that a trypsin-like protease is one of the enzymes responsible for the hydrolysis. Vo et al. (1984) detected a high and stable level of activity of intestinal amino peptidase during the production of fish sauce. Del Rosario and Maldo (1984) measured the activity of four different proteases in fish sauce produced from horse mackerel. During a four-month period of measurement, they found the activity of cathepsins A, C, and B to be stable and that of cathepsin D to decrease. Raksakulthai and Haard (1992) found that cathepsin C obtained from capelin was active in the presence of 20–25% salt, suggesting that this enzyme is involved in the hydrolysis of capelin fish sauce. These studies indicate that several different proteases need to be active and that their concerted action is necessary to achieve the pronounced hydrolysis required for production of such fish sauces.

It is notable that the similarly high storage temperatures present in southern Europe do not lead to a solubilization of salted sardines and anchovies. Ishida et al. (1994) reported that at 35°C salted Japanese anchovies *(Eriobotrya japonica)* degraded to a marked degree, whereas at this temperature salted anchovies from southern Europe *(E. encrasicolus)* were structurally stable. Also, they detected a thermostable trypsin-like proteinase in the muscle of both salted Japanese anchovies and European anchovies, but its activity was much higher in the Japanese anchovies. An explanation of the difference between the European and the Asian products might be a large difference between the hydrolytic enzyme activity of the respective raw materials.

PRODUCTION OF SURIMI

Surimi is basically a myofibrillar protein concentrate that forms a gel due to cross-linking of its actomyosin molecules (An et al. 1996). It is made from minced fish flesh obtained mainly from pelagic white fish of low fat content, such as Alaskan pollack and Pacific whiting. The mince is washed several times with water to remove undesired elements such as connective tissue and lipids. The particulate is then stabilized by cryoprotectants before being frozen (Park and Morrisey 2000).

Surimi is used as a raw material for the manufacture of various products, such as imitation crabmeat and shellfish substitutes.

The manufacture of surimi products involves the use of a slow temperature-setting process, which can be in the temperature range of 4–40°C, followed by a heating process involving temperatures of 50–70°C, which results in the gel strength being enhanced (Park 2000). Surimi-based products are very important fish products in the Asian and Southeast Asian countries, where Japan has the largest production and marketing of surimi-based products. The quality and the price are closely dependent on the gel strength (Park 2000).

The enzyme transglutaminase plays an important role in the gelation process through catalyzing the cross-linking of the actomyosin (An et al. 1996). Some of the differences in gelling capability among different species are due to the properties and levels of activity of muscle transglutaminase (An et al. 1996, Lanier 2000). Studies have shown that the addition of microbial transglutaminase can increase the gel strength obtained in fish species having low transglutaminase activity (Perez-Mateos et al. 2002, Sakamoto et al. 1995). The effect of transglutaminase on the processing of surimi has been reviewed extensively by An et al. (1996) and by Ashie and Lanier (2000).

A softening of the gel during the temperature-setting and heating processes can occur due to auto-lysis of the myosin and actomyosin through the action of endogenous heat-stable proteinases. Whether or not this occurs is partly a function of the species used for the surimi production. Two groups of proteinases have been identified as being responsible for the softening: cysteine cathepsin and HAP.

The presence of HAP in the muscle of different fish species used for surimi production and the effects it has on degradation of the fish gel during the heating process have been taken up in a number of studies (Makinodan et al. 1985, Toyahara et al. 1990, Cao et al. 1999). The finding of Kinoshita et al. (1990b) that the fish species differ in the amount of HAP in muscle, could partly explain why softening of the gel is more pronounced in some fish species than in others.

A study by An et al. (1994) indicated that the cysteine proteinase cathepsin L contributes to degradation of the myofibrils in surimi at a temperature of about 55°C during the heating process, a result substantiated by Ho et al. (2000), who also measured the softening of mackerel surimi upon the addition of mackerel cathepsin L.

TECHNOLOGICAL APPLICATIONS OF ENZYMES FROM SEAFOOD

Utilization of enzymes from seafood as technical aids in both seafood processing and other areas of food and feed processing has been an area of active research for many years. There are two factors that have provided the primary motivation for such research: (1) the cold-adaptation properties of seafood enzymes and (2) the increasing production of marine by-products used as potential sources of enzymes. Although the results have been promising, many of the potential technologies are still in their initial stages of development and are not yet fully established industrially.

IMPROVED PROCESSING OF ROE

Roe is considered by many to be a seafood delicacy. Russian caviar, produced from the roe of sturgeon, is the form best known, although roe produced from a variety of other species, such as salmon, trout, herring, lumpfish, and cod, has also gained wide acceptance. The roe is originally covered by a two-layer membrane (chorion) termed the roe sack. In some species, mechanical or manual separation of the roe from the sack results in damage to the eggs and in yields as low as 50% (Gildberg 1993). Pepsin-like proteases isolated from the intestines of seafood species, as well as collagenases from the hepatopancreas of crabs, have been shown to cleave the linkages between the sac and the eggs without damaging the eggs. Such enzyme treatment has been reported to increase the yield from 70% to 90% (Gildberg et al. 2000, and references therein).

PRODUCTION OF FISH SILAGE

Fish silage is a liquid nitrogenous product made from small pelagic fish or fish by-products mixed with acid. It is used as a source of protein in animal feed (Aranson 1994, Gildberg 1993). In its manufacture, the fish material is mixed with 1–3.5% formic acid solution, reducing pH to 3–4. This is optimal for the intestinal proteases and aspartic muscle proteases contained in the fish material, allowing the solubilization of the fish material to proceed as an autolytic process driven by both types of protease (Gildberg et al. 2000). Gildberg and Almas (1986) have reported the existence of two very active pepsins (I and II) in silage manufactured from cod viscera. They were able to show that fish by-products having low protease activity could be hydrolyzed and used for silage by adding protease-rich cod viscera.

DESKINNING AND DESCALING OF FISH

Deskinning fish enzymatically can increase the edible yield as compared with that achieved by mechanical deskinning (Gildberg et al. 2000). It also provides the possibility of utilizing alternative species such as skate, the skin of which is very difficult to remove mechanically without ruining the flesh (Stefánsson and Steingrimsdottir 1990). It has been shown that herring can be deskinned enzymatically by use of acid proteases obtained from cod viscera (Joakimsson 1984). Enzymatic removal of the skin of other species has been reported as well. Kim et al. (1993) have described removal of the skin of filefish by use of collagenase extracted from the intestinal organs of the fish. Crude protease extract obtained from minced arrowtooth flounder has been found to be effective in solubilizing the skin of pollock (Tschersich and Choudhury 1998).

Removing squid skin can be a difficult task. Skinning machines only remove the outer skin of the squid tubes, leaving the tough rubbery inner membrane. Strom and Raa (1991) reported a gentler and more efficient enzymatic method of deskinning the squid, using digestive enzymes from the squid itself. Also, a method for deskinning the squid by making use of squid liver extract has been developed by Leuba et al. (1987).

For certain markets, such as Japanese sashimi restaurants and fresh fish markets, skin-on fillets without the scales are demanded. Also, fish skin is used in the leather industry, where descaling is likewise necessary. Obtaining a prime quality product requires gentle descaling. Mechanical descaling can be difficult to accomplish without the fish flesh being damaged, especially in the case of certain soft-fleshed species, where enzymatic descaling results in a gentle descaling (Svenning et al. 1993). Digestive enzymes of fish have proved to be useful for removing scales gently (Gildberg et al. 2000).

IMPROVED PRODUCTION OF FISH SAUCE

As already indicated, the original process for manufacturing fish sauce is carried out at high ambient temperature, involving the use of an autolytic process catalyzed by endogenous proteases. The rate of the hydrolysis depends on the content of digestive enzymes in the fish. There has been an obvious interest, however, in shortening the time required for producing the fish sauce, and use has also been made of other fish species, such as Arctic capelin and Pacific whiting. Arctic capelin is usually caught during the winter, when the fish has a low feed intake and its digestive enzyme content thus is low. Research has shown, however, that supplementing Arctic capelin with cod intestines or squid pancreas, both of which are rich in digestive enzymes, allows an acceptable fish sauce to be produced during the winter (Gildberg 2001, Raksakulthai et al. 1986). Tungkawachara et al. (2003) showed that fish sauce produced from a mixture of Pacific whiting and surimi by-products (head, bone, guts, and skin from Pacific whiting) has the same sensory quality as a commercial anchovy fish sauce.

SEAFOOD ENZYMES USED IN BIOTECHNOLOGY

The poor temperature stability of seafood enzymes is a useful property that has led to the production of enzymes useful in gene technology, where only very small amounts of enzymes are needed. Alkaline phosphatase from cold-water shrimp *(Pandalus borealis)* is more heat labile than alkaline phosphatases from mammals and can be denatured at 65°C for 15 minutes (Olsen et al. 1991). The heat-labile enzyme is therefore more suitable as a DNA-modifying enzyme in gene-cloning technology, where higher temperatures can denature the DNA. The enzyme is recovered for commercial use from shrimp-processing wastewater in Norway. Other seafood enzymes with heat-labile properties, such as Uracil-DNA *N*-glycosylase from cod (Lanes et al. 2000), and shrimp nuclease, are likewise produced commercially as recombinant enzymes for gene-cloning technology.

POTENTIAL APPLICATIONS OF SEAFOOD ENZYMES IN THE DAIRY INDUSTRY

Research has shown that digestive proteases from fish, due to their specificity, can be useful as rennet substitutes for calf chymosin in cheese making (Brewer et al. 1984, Tavares et al. 1997, Shamsuzzaman and Haard 1985). Due to their heat lability, they can be useful for preventing oxidized flavor from developing in milk (Simpson and Haard 1984). Simpson and Haard (1984) found that cod and bovine trypsin are equally effective in preventing copper-induced off-flavors from developing in milk. But the cod enzyme has the advantage of being completely inactivated after pasteurization at 70°C for 45 minutes, whereas 47% of the bovine trypsin is still active. These studies show that cold-adaption properties of marine enzymes can be an advantage in the processing of different foods.

Seafood Enzymes: Biochemical Properties and Their Impact on Quality

Sappasith Klomklao, Soottawat Benjakul, and Benjamin K. Simpson

Abstract: Recovery and characterization of enzymes from seafood has taken place and this has led to the emergence of some interesting new applications of these enzymes in food processing. The major enzymes isolated from marine organism and used for industrial application are protease, transglutaminase, and lipase. However, some enzymes found in the fish and aquatic invertebrates have exhibited an adverse effect on seafood quality such as polyphenoloxidase and TMAOase. Therefore, appropriate approach to tackle the problem associated with undesirable enzyme has become the technical concern for processors to maintain the prime quality of seafood and seafood products. On the other hand, the maximization of desirable enzyme activities is the means to come across the fulfillment of seafood processing. In addition, the cost of enzyme from other sources could be lowered, leading to the sustainability of seafood industry, in which all resources could be fully utilized.

INTRODUCTION

The marine environment contains a wide variety of genetic material, offering enormous potential as a source of enzymes. Because of the biological diversity of marine species, a wide array of enzymes with unique properties can be recovered and effectively utilized. Most enzymes from fish and aquatic invertebrates are present in terrestrial organisms. However, the enzymes from different marine species, as well as their organs or environment habitat display differences in molecular weight (MW), amino acid composition, pH and temperature optimum, stability, and inhibition characteristics and kinetic properties. Recovery and characterization of enzymes from seafood has been studied extensively, and this has led to the emergence of some interesting new applications of these enzymes in food processing. The major enzymes isolated from marine organisms and used for industrial application are proteases, transglutaminases, and lipases. However, some enzymes found in fish and aquatic invertebrates exhibit adverse effects on seafood quality such as polyphenoloxidases (PPO) and trimethylamine-*N*-oxide demethylase (TMAOases). Therefore, appropriate approaches to tackle the problem associated with undesirable enzymes in seafood products have become a technical concern for processors to maintain the prime quality of seafood and seafood products. Conversely, the activities of desirable enzyme should be maximized to fully exploit the marine resources. Furthermore, the need of commercial enzymes can be reduced, thereby lowering the operation cost associated with those enzymes.

PROTEASES

Proteases play an important role in the growth and survival of all living organisms. Protease catalyzes the hydrolysis of peptide bonds in polypeptides and protein molecules (Garcia-Carreno and Hernandez-Cortes 2000). On the basis of their in vitro properties, proteases have been classified in a number of ways such as the pH range over which they are active (acid, neutral, or alkaline proteases), their ability to hydrolyze specific proteins, and their mechanism of catalysis. Proteases may be classified based on their similarities to well-characterized proteases such as trypsin-like, chymotrypsin-like, chymosin-like or cathepsin-like, and so on (Haard 1990). In addition, proteases are classified according to their catalytic action (endopeptidase or exopeptidase) and the nature of the catalytic site. In Enzyme Commission (EC) system for enzyme nomenclature, all proteases (peptide hydrolases) belong to subclass 3.4, which is further divided into 3.4.11–19, the exopeptidases and 3.4.21–24, the endopeptidases or proteinases (Nissen 1993). Endopeptidases cleave the polypeptide chain at particularly susceptible peptide bonds distributed along the chain, whereas exopeptidases hydrolyze one amino acid unit sequentially from the *N*-terminus (aminopeptidases) or from *C*-terminus (carboxypeptidases) (Fig. 14.1). Exopeptidases, especially aminopeptidases, are ubiquitous, but less readily available as commercial products, since many of them are intracellular or membrane bound (Simpson 2000). For endopeptidases or proteinases, the four major classes of endopeptidases can be distinguished according to the chemical group of their active site, including serine proteinases (EC 3.4.21), thiol or cysteine proteinases (EC 3.4.22), acid or aspartic proteinases (EC 3.4.23), and metalloproteinases (EC 3.4.24) (Simpson 2000). The enzymes in the different classes are differentiated by various criteria, such as the nature of the groups in their catalytic sites, their substrate specificity, and their response to inhibitors or by their activity/stability under acid or alkaline conditions (Nissen 1993).

For marine animals, proteases are mainly produced by the digestive glands. Like the proteases from plants, animals, and microorganisms, digestive proteases from marine animals are polyfunctional enzymes catalyzing the hydrolytic degradation of proteins (Garcia-Carreno and Hernandez-Cortes 2000). For some fish species, proteases are present at high levels in the muscle (Kolodziejska and Sikorski 1996), and are associated with the induced changes of proteins during postmortem storage or processing. Marine animals have adapted to different environmental conditions, and these adaptations, together with inter- and intraspecies genetic variations, are associated with certain unique properties of their proteinases, compared with their counterpart from land animals, plants, and microorganisms (Simpson 2000). Some of these distinctive properties include higher catalytic efficiency at low temperature and lower thermal stability (Klomklao et al. 2009a).

DIGESTIVE PROTEASES FROM MARINE ANIMALS

Digestive proteases have been studied in several species of fish and decapods (De-Vecchi and Coppes 1996). Proteases found in the digestive organs of fish include pepsin, gastricsin, trypsin, chymotrypsin, collagenase, elastase, carboxypeptidase, and carboxyl esterase (Simpson 2000). Pepsin, chymotrypsin, and trypsin are three main groups of proteases found in fish viscera. Pepsin is localized in fish stomach (Klomklao et al. 2007a), while chymotrypsin and trypsin are concentrated in tissues such as the pancreas, pyloric ceca, and intestine (Klomklao et al. 2004). The distribution and properties of protease vary depending on species and organs (Table 14.1). According to the International Union of Applied Biochemists classification, digestive proteases from fish and aquatic invertebrates may be classified into four major groups such as acidic/aspartic protease, serine protease, thiol or cysteine protease, and metalloprotease (Simpson 2000).

Acid/Aspartic Proteases

The acid or aspartic proteases are a group of endopeptidases characterized by high activity and stability at acidic pH. They are referred to as "aspartic" proteases (or carboxyl proteases) because their catalytic sites are composed of the carboxyl group of two aspartic acid residues (Whitaker 1994). On the basis of the EC system, all the acid/aspartic proteases from marine animals have the first three digits in common as EC 3.4.23. Three common aspartic proteases that have been isolated and

characterized from the stomach of marine animals are pepsin, chymosin, and gastricsin (Simpson 2000).

Pepsin, one of the major proteases found in fish viscera, has an extracellular function as the major gastric protease. Pepsin, secreted as a zymogen (pepsinogen), is activated by the acid in stomach to an active form (Klomklao et al. 2007a). The activation of pepsin is initiated by the cleavage of proenzyme either by single step or multiple steps. Nalinanon et al. (2010) reported that pepsinogen from the stomach of albacore tuna was activated within 30–60 minutes under acidic condition, in which protein with MW of 36.8 kDa was found as the intermediate during activation process. Bovine pepsin is composed of a single polypeptide chain of 321 amino acids and has a MW of about 35 kDa (Simpson 2000). However, pepsins from marine animals have been reported to have MWs ranging from 27 to 42 kDa. The MWs of two pepsins (I and II) from orange roughy

stomach were estimated to be approximately 33.5 kDa and 34.5 kDa, respectively (Xu et al. 1996). Sanchez-Chiang et al. (1987) reported that the MWs of two pepsins from stomach of salmon to be approximately 32 kDa and 27 kDa by gel filtration. MWs of two pepsins from polar cod stomachs were estimated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) to be approximately 42 kDa and 40 kDa (Arunchalam and Haard 1985). The MWs of four pepsins from sea bream stomach were determined as approximately 30 kDa by SDS-PAGE (Zhou et al. 2007). Bougatef et al. (2008) reported that pepsin from smooth hound stomach were estimated to be 35 kDa using SDS-PAGE and gel filtration. The MWs of three pepsins from the stomach of European eel were determined as 30 kDa (Wu et al. 2009). Klomklao et al. (2007a) reported that pepsin A and B from stomach of pectoral rattail (*Coryphaenoides pectoralis*) had apparent MWs of 35 kDa and 31 kDa, respectively,
Figure 14.2. Protein pattern of purified pepsins A and B from pectoral rattail stomach determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. M, MW standard; lane 1, pepsin A; lane 2, pepsin B (Klomklao et al. 2007a).

as estimated by SDS-PAGE (Fig. 14.2) and gel filtration on Sephacryl S-200.

Pepsins and pepsin-like enzymes can be extracted from the stomach of marine animals such as capelin (*Mallotus villosus*) (Gildberg and Raa 1983), polar cod (*Boreogadus saida*) (Arunchalam and Haard 1985) sardine (*Sardinops melanostica*) (Noda and Murakami 1981), Monterey sardine (*Sardinops sagax caerulea*) (Castillo-Yanez et al. 2004), sea bream (*Sparus latus* Houttuyn) (Zhou et al. 2007), pectoral rattail (*Coryphaenoides pectoralis*) (Klomklao et al. 2007a), smooth hound (*Mustelus mustelus*) (Bougatef et al. 2008), and European eel (*Anguilla anguilla*) (Wu et al. 2009).

Several methods have been described in the literature for the isolation and purification of pepsins from marine animals. Gildberg et al. (1990) purified pepsin from stomach of Atlantic cod (*Gadus morha*) by ammonium sulfate fractionation (20–70% saturation), followed by ion-exchange chromatography using S-Sepharose column. Klomklao et al. (2007a) purified two pepsins, A and B, from the stomach of pectoral rattail by acidification, ammonium sulfate precipitation (30–70% saturation), followed by a series of column chromatographies including Sephacryl S-200, diethylaminoethyl (DEAE)–cellulose and Sephadex G-50. Pepsin from the stomach of smooth hound was purified by 20–70% ammonium sulfate precipitation, Sephadex G-100 gel filtration, and DEAE–cellulose anion exchange chromatogra-

phy (Bougatef et al. 2008). Recently, Wu et al. (2009) isolated pepsins from the stomach of freshwater fish European eel by ammonium sulfate fractionation, column chromatography on anion exchange (DEAE–Sephacel) and gel filtration (Sephacryl S-200 and Superdex G-75).

Pepsin activity is very dependent on pH values, temperatures, and the type of substrate. Hemoglobin is the substrate most commonly used for determination of pepsin activity (De-Vecchi and Coppes 1996, Klomklao et al. 2004). Pepsin from polar cod stomach exhibited a maximal activity against hemoglobin at pH 2.0 and 37°C (Arunchalam and Haard 1985). Gildberg et al. (1990) reported that the optimal pH of Atlantic cod pepsin for hemoglobin hydrolysis was 3.0. Fish pepsins were shown to hydrolyze hemoglobin much faster than casein (Gildberg and Raa 1983). Most fish species contain two or three major pepsins with an optimum hemoglobin digestion at pH between 2 and 4 (Gildberg and Raa 1983). Gildberg et al. (1990) found that the affinity of cod pepsin, especially pepsin I toward hemoglobin, was lower at pH 2 than at pH 3.5. Klomklao et al. (2007a) found that pepsins A and B from pectoral rattail stomach had maximal activity at pH 3.0 and 3.5, respectively, and had the same optimal temperature at 45°C using hemoglobin as the substrate. Pepsins I, II, and III purified from the stomach of European eel showed maximal activity at pH 3.5, 2.5, and 2.5, respectively, with hemoglobin as substrate (Wu et al. 2009). Bougatef et al. (2008) found that the optimal pH and temperature for the pepsin activity of smooth hound stomach were pH 2.0 and 40°C, respectively, using hemoglobin as a substrate.

Pepsins from marine species are quite stable from pH 2 to about 6, but rapidly lose activity at pH 6 and above due to the denaturation (Simpson 2000). Pepsin from sardine stomach was stable between pH 2 and 6 and showed drastic loss of activity at pH 7.0 (Noda and Murakami 1981). Castillo-Yanez et al. (2004) found that Monterey sardine acidic pepsin-like enzymes were stable at pH ranging from 3.0 to 6.0. Smooth hound pepsin was stable within the pH range of 1.0–4.0 (Bougatef et al. 2008). Klomklao et al. (2007a) also reported that both pepsins A and B from the stomach of pectoral rattail were stable in the pH range of 2.0–6.0. Pepsin from the stomach of albacore tuna was stable in the pH range of 2–5 (Nalinanon et al. 2010).

Chymosins (EC 3.4.23.4), commonly known as rennins, have also been described as acid proteases with some characteristics distinct from other acid proteases (Shahidi and Kamil 2001). For example, these enzymes are most active and stable around pH 7.0 unlike other acid proteases. They also have relatively narrower substrate specificity, compared with other acid proteases such as pepsin (Simpson 2000). Digestive proteases with chymosin-like activity were purified as zymogens from the gastric mucosa of young and adult seals (*Pagophilus groenlandicus*) (Shamsuzzaman and Haard 1984) by a series of chromatographies including DEAE–Sephadex A-50, Sephadex G-100, and Z-D-Phe-T-Sepharose gel. The enzyme had optimal pH of 2.2–3.5 for hemoglobin hydrolysis. The chymosins from marine animals did not hydrolyze the specific synthetic substrate for pepsin (i.e., *N*-acetyl-L-phenylalanine diiodotyrosine) and were also more susceptible to inactivation by urea (Simpson 2000).

Gastricsins, like pepsins, are aspartic proteases that have many properties in common with other enzymes in the family of gastric proteases. However, they differ from pepsins in structure and certain catalytic properties (Simpson 2000). Sanchez-Chiang and Ponce (1981) isolated and characterized two gastricsin isozymes from the gastric juices of hake (*Merluccius gayi*). The optimum pH for the hydrolysis of hemoglobin by hake gastricsins was 3.0, which is similar to that of mammalian gastricsins. Hake gastricsins were stable up to pH 10 but were rapidly inactivated at higher pH values (Sanchez-Chiang and Ponce 1981). The latter property would appear to distinguish the gastricsins from pepsins (Simpson 2000).

Serine Proteases

Serine proteases have been described as a group of endopeptidases with a serine residue, together with an imidazole group and aspartyl carboxyl group in their catalytic sites (Simpson 2000). The proteases in serine subclass all have the same first three digits: EC 3.1.21. A survey of proteolytic enzymes in various species of fish digestive tracts has revealed that serine proteases distributed in fish intestine possess high activity under alkaline rather than neutral pH (Shahidi and Kamil 2001). Among the serine proteases, trypsin, and chymotrypsin are the major serine proteases found in the digestive glands of marine animals.

Trypsins (EC 3.4.21.4) specifically hydrolyze proteins and peptides at the carboxyl side of arginine and lysine residues (Klomklao et al. 2006a). Trypsins play major roles in biological processes including digestion, activation of zymogens of chymotrypsin and other enzymes (Cao et al. 2000). Trypsins from marine animals resemble mammalian trypsins with respect to their molecular size (22–30 kDa), amino acid composition, and sensitivity to inhibitors. Their pH optima for the hydrolysis of various substrates were from 7.5 to 10.0, while their temperature optima for hydrolysis of those substrates ranged from 35°C to 65°C (De-Vecchi and Coppes 1996).

A number of studies on trypsins from fish viscera have been carried out. Two anionic trypsins (trypsin A and trypsin B) from the hepatopancreas of carp were purified using a series of chromatographies including DEAE–Sephacel, Ultrogel AcA54, and Q-Sepharose (Cao et al. 2000). Trypsin A was purified to homogeneity with a MW of 28 kDa, while trypsin B showed two close bands of 28.5 kDa and 28 kDa on SDS-PAGE. Trypsins A and B had optimal activity at 40°C and 45°C, respectively, and had the optimum pH of 9.0 using Boc-Phe-Ser-Arg-MCA as a substrate. Both enzymes were effectively inhibited by trypsin inhibitors. Trypsin from the pyloric ceca of Monterey sardine (*Sardinops sagax caerulea*) with MW of 25 kDa was purified and characterized by Castillo-Yanez et al. (2005). The optimum pH for activity was 8.0 and the maximal activity was found at 50°C. The purified enzyme was partially inhibited by 1.4 mg/mL phenylmethylsulfonyl fluoride and fully inhibited by 0.5 mg/mL soybean trypsin inhibitor or 2.0 mg/mL benzamidine, but was not inhibited by the metalloprotease inhibitor, 0.25 mg/mL ethylenediaminetetraacetic acid (EDTA.) In addition, trypsin was reported to be the major form of protease in the spleen of tongol tuna (*Thunnus tongol*) based on the MW, the inhibition by *N*-*p*-tosyl-L-lysine

chloromethyl ketone (TLCK) and the activity toward specific substrates (Klomklao et al. 2006a). Two anionic trypsins (A and B) were purified from yellowfin tuna (*Thunnus albacores*) spleen. Trypsins A and B exhibited the maximal activity at 55°C and 65°C, respectively, and had the same optimal pH at 8.5 using *N*-*p*-tosyl-L-arginine methyl ester hydrochloride (TAME) as a substrate (Klomklao et al. 2006b). Klomklao et al. (2007d) purified trypsins from skipjack tuna (*Katsuwonus pelamis*) spleen by a series of chromatographies including Sephacryl S-200, Sephadex G-50, and DEAE-cellulose. Skipjack tuna spleen contained three trypsin isoforms, trypsins A, B, and C. The MW of all trypsin isoforms was estimated to be 24 kDa by size exclusion chromatography on Sephacryl S-200 and SDS-PAGE. The optimum pH and temperature for TAME hydrolysis of all trypsin isoforms were 8.5°C and 60°C, respectively.

Recently, Klomklao et al. (2009a) purified two isoforms of trypsin (A and B) from the intestine of skipjack tuna (*Katsuwonus pelamis*) by Sephacryl S-200, Sephadex G-50, and DEAE–cellulose. The MWs of both trypsins were 24 kDa as estimated by size exclusion chromatography and SDS-PAGE. Trypsin A and B exhibited maximal activity at 55°C and 60°C, respectively, and had the same optimal pH at 9.0. Trypsin from the pyloric ceca of pectoral rattail (*Coryphaenoides pectoralis*) was purified and characterized (Klomklao et al. 2009b). Purification was carried out by ammonium sulfate precipitation, followed by column chromatographies on Sephacryl S-200, DEAE–cellulose, and Sephadex G-50. Purified trypsin had an apparent MW of 24 kDa when analyzed using SDS-PAGE and size exclusion chromatography. Optimal profiles of pH and temperature of the enzyme were 8.5°C and 45°C, respectively, using TAME as substrate (Fig. 14.3).

Trypsins from marine animals tend to be more stable at alkaline pH, but are unstable at acidic pH, and in this respect differ from trypsins from mammals that are most stable under acidic condition (Simpson 2000, Klomklao et al. 2006a). Trypsin from tongol tuna spleen showed high pH stability within the range of pH 6–11, but the inactivation was more pronounced at pH values below 6 (Klomklao et al. 2006a). Klomklao et al. (2007d) reported that skipjack tuna spleen trypsins were stable in the pH ranging from 6.0 to 11.0 but were unstable at pH below 5.0. Also, trypsin purified from the pyloric ceca of pectoral rattail was stable in a wide pH range of 6–11 but unstable at pH below 5.0 (Klomklao et al. 2009b). The stability of trypsins at a particular pH might be related to the net charge of the enzyme at that pH (Castillo-Yanez et al. 2005). Trypsin might undergo the denaturation under acidic conditions, where the conformational change took place and enzyme could not bind to the substrate properly (Klomklao et al. 2006a, 2006b). For thermal stability, the thermal stability of fish trypsin varies with species as well as with incubation conditions (De-Vecchi and Coppes 1996).

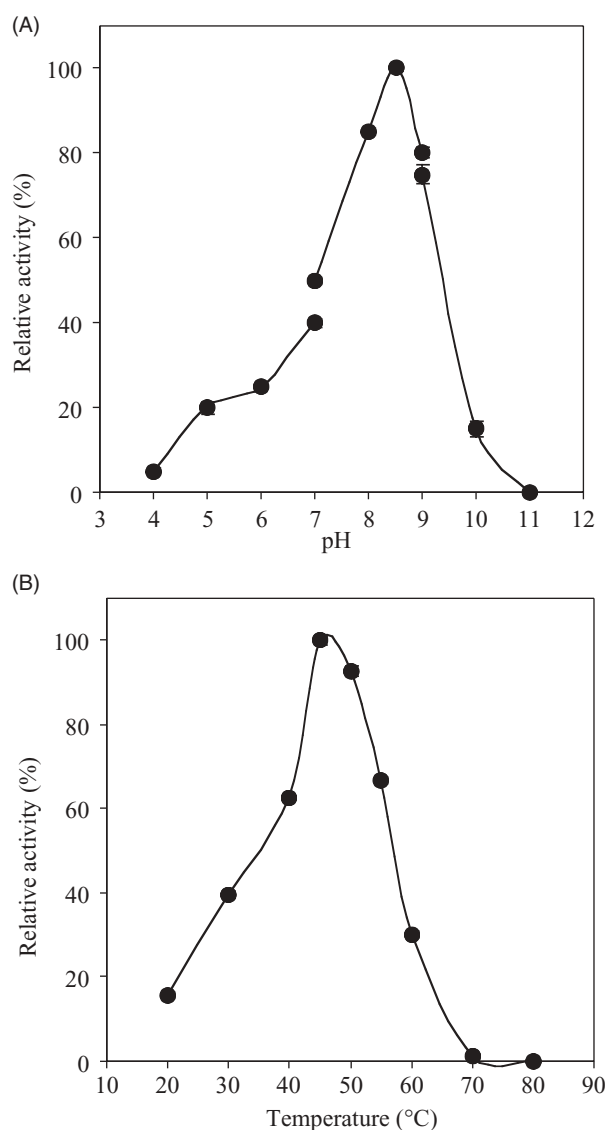
N-terminal amino acid sequences are useful as tools to identify the type of enzymes and may be useful for designing primers for cDNA cloning of enzyme (Cao et al. 2000, Klomklao et al. 2007b). Table 14.2 shows the *N*-terminal amino acid sequences of fish trypsins compared with those of mammals. Generally, fish trypsins had a charged Glutamic acid residue at position 6, where threonine (Thr) is most common in mammalian pancreatic


Figure 14.3. pH **(A)** and temperature **(B)** profiles of purified trypsin from the pyloric ceca of pectoral rattail (Klomklao et al. 2009b).

trypsins (Table 14.2). Moreover, the sequence of all trypsins starts with IVGG after limited proteolysis of inactive trypsinogen into the active trypsin (Cao et al. 2000, Klomklao et al. 2006b).

Chymotrypsin is another member of a large family of serine proteases functioning as a digestive enzyme. Chymotrypsins have been isolated and characterized from marine species such as anchovy (Heu et al. 1995), Atlantic cod (Asgeirsson and Bjarnason 1991), scallop (Chevalier et al. 1995), Monterey sardine (Castillo-Yanez et al. 2006), and crucian carp (Yang et al. 2009). In general, these enzymes are single-polypeptide molecules with MWs between 25 kDa and 28 kDa. They are most active within the pH range of 7.5–8.5 and are most stable at around pH 9.0 (Simpson 2000). Chymotrypsins have a much broader specificity than trypsins. They cleave peptide bonds involving amino

acids with bulky side chains and nonpolar amino acids such as tyrosine (Tyr), phenylalanine, tryptophan, and leucine (Simpson 2000).

Thiol/Cysteine Proteases

Thiol or cysteine proteases are a group of endopeptidases that have cysteine and histidine residues as the essential groups in their catalytic sites. These enzymes require the thiol (-SH) group furnished by the active site cysteine residue to be intact, hence, this group is named "thiol" or "cysteine" proteases (Simpson 2000). The thiol proteases are inhibited by heavy metal ions and their derivatives, as well as by alkylating agents and oxidizing agents (Simpson 2000). The first three digits common to thiol proteases are EC 3.4.22.

Digestive cysteine proteases have been found in the viscera of fish and aquatic invertebrates. Digestive cysteine proteases from marine animals are most active at acidic pH and inactive at alkaline pH. Cathepsin B, cathepsin L, and cathepsin S are common examples of digestive thiol protease from marine animals (Simpson 2000). Various researchers have described different procedures for isolating marine cysteine or thiol proteases from the digestive glands of marine animals.

Cathepsin B was isolated from a few aquatic animals including the horse clam (Reid and Rauchert 1976), mussel (Zeef and Dennison 1988), and carp (Aranishi et al. 1997a). Generally, cathepsin B from marine animals is a single polypeptide chain with molecular sizes ranging from 13.6 to 25 kDa. Cathepsins from different species show maximum activity over a broad pH range of 3.5–8.0. Cathepsin B is activated by Cl^- ions, and requires sulfhydryl-reducing agents or metal-chelating agents for activity (Zeef and Dennison 1988).

Cathepsin L from carp hepatopancreas was purified by using ammonium sulfate precipitation and a series of chromatographies, in which the enzyme had an affinity toward Concanavalin A and Cibacron Blue F3GA (Aranishi et al. 1997b). Its homogeneity was established by a native-PAGE. Two protein bands corresponding to MWs of 30 kDa and 24 kDa were found on SDS-PAGE. The enzyme exhibited a maximal activity against Z-Phe-Arg-MCA at pH 5.5–6.0 and 50°C. All tested cysteine protease inhibitors, TLCK and chymostatin, markedly inhibited its activity, whereas the other serine protease inhibitors and metalloprotease inhibitors showed no inhibitory effects on the enzyme (Aranishi et al. 1997b). Recently, Cardenas-Lopez and Haard (2009) isolated cathepsin L from jumbo squid hepatopancreas by a two-step procedure involving ammonium sulfate precipitation and gel filtration chromatography. The MW of the enzyme was 24 kDa determined by SDS-PAGE and 23.7 kDa by mass spectrometry. The activity had an optimum pH of 4.5 and optimum temperature of 55°C using benzyloxycarbonyl-Phe-Arg-7-amino-4-trifluoro methyl coumarin as substrate.

Cathepsin S from hepatopancreas of carp (*Cyprinus carpio*) was purified by ammonium sulfate fractionation, followed by SP-Sepharose, Sephacryl S-200, and Q-Sepharose, respectively, (Pangkey et al. 2000). The MW of purified protease was 37 kDa estimated by SDS-PAGE. It hydrolyzed Z-Phe-Arg-MCA but not Z-Arg-MCA. The optimal pH and

temperature for the hydrolysis of Z-Phe-Arg-MCA were 7.0 and 37°C, respectively. This protease activity was inhibited by E-64, leupeptin, 5–5'-dithiobis (2-nitro-benzoic acid), and *p*-tosyl-lys-chloromethylketone.

Metalloproteases

The metalloproteases are hydrolytic enzymes whose activity depends on the presence of bound divalent cations (Simpson 2000). There may be at least one tyrosyl residue and one imidazole residue associated with the catalytic sites of metalloproteases (Whitaker 1994). The metalloproteases are inhibited by chelating agents such as 1, 10-phenanthroline, EDTA, and sometimes by the simple process of dialysis. The metalloproteases have been characterized from marine animals (e.g., rockfish, carp, and squid mantle) but have not been found in the digestive glands except in the muscle tissue (Simpson 2000). Metalloproteases do not seem to be common in marine animals (Simpson 2000). However, Sivakumar et al. (1999) purified collagenolytic metalloprotease with gelatinase activity from carp hepatopancreas by ammonium sulfate fractionation and gel filtration chromatography. The enzyme had a MW of 55 kDa and was active against native type I collagen. Optimum temperature and pH were 25°C and 7–7.5, respectively. The enzyme was strongly inactivated by 10 mM EDTA.

MUSCLE PROTEASES FROM MARINE ANIMALS

Muscles of marine animals contain a variety of proteases. These enzymes perform different metabolic functions in the living organisms. Their activity depends on the species, life cycle, and the feeding status of the animal (Kolodziejska and Sikorski 1996). Endogenous proteases in fish muscle are found in the sarcoplasmic (or soluble) component of muscle tissues, in association with cellular organelles, connective tissues, and myofibrils and in the interfiber space (Kolodziejska and Sikorski 1996). A number of endogenous proteases have been investigated as enzymes contributing to postmortem softening of fish flesh, which also participate to a different extent in the degradation of myofibrillar protein (Visessanguan et al. 2001). The action of these enzymes exerts detrimental effects on the sensory quality and functional properties of muscle food (Visessanguan et al. 2001). The muscles of marine fish and invertebrates contain lysosomal cathepsins, as well as different proteases active in neutral and alkaline range of pH (Table 14.3).

Cathepsins

Lysosomal proteases such as cathepsin A (carboxypeptidase A), cathepsin B (carboxypeptidase B), cathepsin D, cathepsin H, and L have been recovered and identified from various fish and aquatic invertebrates (Shahidi and Kamil 2001). Except for cathepsin D, all other lysosomal proteases belong to serine or cysteine (thiol). However, cathepsin D, which is an aspartic protease, has its pH optimum within the acidic range (Simpson 2000).

Cathepsin A (EC 3.4.16.1) is now called carboxypeptidase A. The enzyme has a pH optimum of 5–6 and is readily inactivated by heat and alkaline, and has a molecular mass of about 35 kDa. Cathepsin A has been purified about 1700-fold to homogeneity from carp muscle (Toyohara et al. 1982). The molecular mass was estimated to be 36 kDa and the pH optimum was 5.0.

Table 14.3. Muscle Proteases from Marine Animals

Major Group	Family	Enzyme	Purified Organism	Reference
Lysosomal cathepsin	Cysteine	Cathepsin A	Carp	Toyohara et al. (1982)
			Milkfish	Jiang et al. (1990)
			Atlantic cod	McLay (1980)
		Cathepsin B	Carp	Makinodan and Ikeda (1971)
			Grey mullet	Bonete et al. (1984)
			Tilapia	Sherekar et al. (1988)
			Mackerel	Aoki et al. (2002)
		Cathepsin C	Atlantic squid	Hameed and Haard (1985)
			Pacific whiting	Erickson et al. (1983)
		Cathepsin L	Chum salmon	Yamashita and Konagaya (1990)
			Spotted mackerel	Lee et al. (1993)
			Anchovy	Heu et al. (1997)
			Pacific whiting	Visessanguan et al. (2001)
	Aspartic	Cathepsin D	True sardine	Klomklao et al. (2008)
			Herring	Nielsen and Nielsen (2001)
Alkaline proteases	Serine	Trypsin-like	Atlantic menhaden	Choi et al. (1999)
			Bigeye snapper	Benjakul et al. (2003a)
Neutral proteases	Cysteine	Calpains	Tilapia	Wang et al. (1993)
			Octopus	Hatzizisis et al. (1996)
			Sea bass	Ladrat et al. (2000)
			Rainbow trout	Saito et al. (2007)
	Metalloprotease	Neutral metalloprotease	Crucian carp	Kinoshita et al. (1990)

Two cathepsin A-like proteases (15.6 kDa and 35.6 kDa) have been purified from milkfish muscle and had optimal activity with carbobenzoyl-L-Gly-L-Phe at pH 7.0 (Jiang et al. 1990). Cathepsin A, partially purified from Atlantic cod muscle, hydrolyzed carbobenzoyl-α-Glutamyl-L-Tyr with an optimum of pH 5.0 (McLay 1980). Cathepsin A-like activity has also been detected in muscle of tilapia, Bombay duck, pomfret, and shrimp by Sherekar et al. (1988) but was not detected in cod muscle (Shahidi and Kamil 2001).

Cathepsin B (EC 3.4.22.1) is the best known and most thoroughly investigated lysosomal thiol protease. It is now recognized that at least two enzymes have this activity including cathepsin B (B_1) and B_2. Cathepsin B_1 is a thiol endopeptidase, having a MW of 24–28 kDa with a pH of 5.0–5.2, and maximal activity at pH 6.0. In contrast, cathepsin B_2 is an exopeptidase also called carboxypeptidase B, with a MW ranging between 47 kDa and 52 kDa (Kang and Lanier 2000). Cathepsin B_3, now called cathepsin H, is a 25-kDa glycoprotein that is very heat stable. Cathepsin B purified from carp (Makinodan and Ikeda 1971), grey mullet (Bonete et al. 1984), tilapia (Sherekar et al. 1988), and mackerel (Aoki et al. 2002) had the MWs of 23–29 kDa and optimal pH range of 5.5–6.0. Aoki et al. (2002) reported that cathepsin B purified from the white muscle of common mackerel had a MW of 23 kDa. The optimal pH for activity was 5.5.

Cathepsin C (EC 3.4.4.9), an exopeptidase, is also called dipeptidyl transferase and dipeptidyl-aminopeptidase. It was first recognized as an enzyme that deaminates Gly-Phe-NH$_2$. It is unlikely to act on intact proteins directly, but rather has the highest specific activity among all the lysosomal peptidase, suggesting that it further digests the resulting peptide fragments by cathepsin D. It is an oligomeric thiol protease with a MW of 200 kDa requiring Cl$^-$ ions for activity (Ashie and Simpson 1997). The enzyme is optimally active within a pH range of 5–6 (Ashie and Simpson 1997). Hameed and Haard (1985) reported that cathepsin C extracted from Atlantic squid muscle had MW of 25 kDa and was Cl$^-$ and sulfhydryl dependent, being inhibited by sulfhydryl enzyme inhibitors, such as iodoacetate, PCMB, and HgCl$_2$. For cathepsin C from sarcoplasmic fluid of Pacific whiting, it showed the maximal activity at pH 7.0, which was greater than the maximal activity obtained at pH 6.0 in cod (Erickson et al. 1983).

Cathepsin D (EC 3.4.4.23) is a major lysosomal aspartic protease, which is involved in the cellular degradation of proteins (Nielsen and Neilsen 2001). Cathepsin D is a 42–60 kDa endopeptidase that is active within a pH range of 3–5. It exists in several isomeric forms with pH ranging between 5.7 and 6.8, and exhibits a broad range of activity on muscle tissue between pH 3.0 and 6.0 (Ashie and Simpson 1997). The enzyme preferentially cleaves peptide bonds between hydrophobic amino acid residues (Ashie and Simpson 1997). Cathepsin D is strongly inhibited by pepstatin A, a specific inhibitor of carboxyl proteases, whereas thiol protease inhibitors have negligible effects on enzyme activity (Bonete et al. 1984). Cathepsin D was purified from herring muscle. The purified enzyme is a monomer with a MW of 38–39 kDa. It is inhibited by pepstatin and has an optimal activity at pH 2.5 when hemoglobin is used as the substrate. The isoelectric point is 6.8 (Nielsen and Nielsen 2001). Klomklao

et al. (2008) reported that the predominant enzyme responsible for autolysis in true sardine was a cathepsin D, which exhibited the maximal activity at 55°C, pH 3.5 and was effectively inhibited by pepstatin A.

Cathepsin L (EC 3.4.22.15), is a typical cysteine protease found in lysosomes and is considered to have major biological roles in proteolysis. It is a 24-kDa molecule, existing in multiple forms with pH between 5.9 and 6.1 and it exhibits the activity in a wide range of pH (3.0–6.5). It is strongly inhibited by iodoacetate, leupeptin, and antipain (Kang and Lanier 2000). Visessanguan et al. (2003) purified cathepsin L from arrowtooth flounder muscle by heat treatment, followed by a series of chromatographic separations. The apparent molecular mass of the purified enzyme was 27 kDa by size exclusion chromatography and SDS-PAGE. The enzyme had high affinity and activity toward Z-Phe-Arg-NMec. Activity was inhibited by sulfhydryl reagents and activated by reducing agents. The purified enzyme displayed optimal activity at pH 5.0–5.5 and 60°C, respectively. Cathepsin L from the muscle of anchovy was purified and characterized (Heu et al. 1997). The enzyme was activated by thiol reagents and inhibited by thiol-blocking reagents. The MW was estimated to be 25.8 kDa by SDS-PAGE. The enzyme exhibited its maximal activity at pH 6.0 and 50°C. Cathepsin L is a major protease, which degrades myofibrillar proteins in antemortem or postmortem muscle of chum salmon (Yamashita and Konagaya 1990), spotted mackerel (Lee et al. 1993), and Pacific whiting (Visessanguan et al. 2001). Cathepsin L is capable of hydrolyzing a broad range of proteins including myosin, actin, nebulin, cytosolic proteins, collagen, and elastin (Visessanguan et al. 2001).

Alkaline Proteases

Alkaline proteases are located in the muscle sarcoplasm, microsomal fraction or are bound to myofibrils (Makinodan and Ikeda 1971). Alkaline proteases are active at neutral to slightly alkaline pH and are unstable under acidic conditions (Simpson 2000). They are sometimes characterized as trypsin-like serine enzyme, which show great capacity of degrading intact myofibrils in vitro (Busconi et al. 1987). Generally, alkaline proteases are heat stable and also become active at the neutral pH of fish meat paste. Properties of alkaline proteases vary with sources. Alkaline proteases are oligomeric protease with high MWs ranging from 560 to 920 kDa (Kolodziejska and Sikorski 1996). However, an alkaline protease isolated from Atlantic croaker was much smaller with MW of 80–84 kDa (Lin and Lanier 1980). These enzymes normally exhibit little or no catalytic activity unless assayed at a nonphysiologically high temperature (60–65°C) or activated by protein denaturing agents such as urea, fatty acids, or detergents (Visessanguan et al. 2001). Two alkaline proteases (A and B) were purified from Atlantic menhaden muscle (Choi et al. 1999). The MWs of purified enzymes were 707 kDa and 450 kDa, respectively. Both are probably serine proteases, and optimum caseinolytic activity was observed at pH 8 and 55°C. Purification of a novel myofibril-bound serine protease from the ordinary muscle of the carp was carried out by solubilizing it from the myofibril fraction with acid treatment, followed by

Ultrogel AcA 54 and Arginine-Sepharose 4B chromatography (Osatomi et al. 1997). The MW of purified enzyme was 30 kDa by SDS-PAGE and gel filtration. The optimum pH and temperature of the enzyme were 8.0 and 55°C, respectively. Benjakul et al. (2003a) reported that heat stable alkaline proteases purified from bigeye snapper had the optimum pH and temperature for casein hydrolysis at 8.5 and 60°C, respectively. The MW of purified enzyme was estimated to be 72 kDa by gel filtration.

Neutral Ca^{2+}-Activated Proteases

Neutral proteases in skeletal muscle have been classified with the Ca^{2+}-activated, neutral endopeptidases known as CANP, and recently as calpains (EC 3.4.33.17) (Kolodziejska and Sikorski 1996). These enzymes are further subclassified into μ-calpain and m-calpain, which differ in sensitivity to calcium ions. Both are heterodimers: the large subunit and the small subunit for μ- and m-calpain, which have MWs near 80 kDa and 28 kDa, respectively (Cheret et al. 2007). The calcium requirement of μ- and m-calpain was 50–70 μM and 1–5 mM, respectively. Calpastatin is known to be the endogenous specific inhibitor of calpain (Kolodziejska and Sikorski 1996). Calpains have been isolated and characterized from the muscles of seafood species like carp, American lobster, and scallop (Toyohara et al. 1982, Kolodziejska and Sikorski 1996). Wang et al. (1993) purified m-calpains from tilapia muscle by Phenyl-Sepharose CL-4B, Sephacryl S-200, Q-Sepharose, and Superose 12 HR column chromatography. The enzyme had a MW of 110,000 containing two subunits of 80 kDa and 28 kDa. It has optimal temperature and pH of 30°C and 7.5, respectively. The protease was activated by dithiothreitol, glutathione, and β-mercaptoethanol and was inhibited by calpain inhibitor I, calpain inhibitor II, leupeptin, antipain, iodoacetic acid, but not affected by pepstatin A and N-ethylmaleimide. Calpain was purified to homogeneity from the arm muscle of *Octopus vulgaris* (Hatzizisis et al. 1996). The enzyme consists of a 65-kDa protein when separated by SDS-PAGE. The Ca^{2+} requirements for its half maximal and maximal activities are 1.5 mM and 7 mM, respectively. It is strongly inhibited by thiol protease inhibitors such as leupeptin, E-64, and antipain and by alkylating agents such as iodoacetic acid and iodoacetamide. The enzyme displayed maximal activity at 30°C and showed broad pH optimum between 6.5 and 7.5.

Fish Protease Applications

Proteases are by far the most studied enzymes for industrial bioprocessing. Almost half of all industrial enzymes are proteases, mostly used in the detergent, leather, and food industries (Klomklao et al. 2005). The food industry uses proteases as processing aids for many products including baked goods, beer, wine, cereals, milk, fish products, and legumes. Production of protein hydrolysates and flavor extracts has been known to be successful by using selected proteases (Table 14.4) (Klomklao 2008).

Commercial supplies of food processing enzymes are presently derived from various plants, animal, and microbial sources. Compared with these enzymes used in food processing,

Table 14.4. Some Uses of Proteolytic Enzymes in Food Industry

Commodity	Application
Cereals, baked goods	Increase drying rate of proteins; improve product handling. Characteristics: decrease dough mixing time; improve texture and loaf volume of bread; and decrease dough mixing time
Egg and egg products	Improve quality of dried products
Meats	Tenderization; recover protein from bones; hydrolysis of blood proteins
Fish	Fish protein hydrolysates, viscosity reduction, skin removal, roe processing, acceleration of fish sauce production, recover carotenoprotein from shrimp shell
Pulses	Tofu; soy sauce; protein hydrolysis; off-flavor removal soy milk
Dairy	Cheese curd formation; accelerate cheese aging; rennet puddings
Brewing	Fermentation and filtration aid; chill proofing
Wine	Clarification; decrease foaming, promote malolactic fermentation
Coco	Facilitate fermentation for chocolate production

the use of proteases from marine fish is still rare. Fish digestive enzymes can be recovered as by-products from fish processing by-products (Haard 1992). However, most proteases from marine animals are extracellular digestive enzymes with characteristics differing from homologous proteases from warm-blooded animals (De-Vecchi and Coppes 1996). They are more active catalysts at relatively low temperature, compared with similar enzymes from mammals, thermophilic organisms, and plants (Klomklao 2008). Low temperature processing could provide various benefits, such as low thermal costs, protection of substrates or products from thermal degradation and/or denaturation, and minimization of unwanted side reactions (Haard 1992). Certain fish enzymes are excellent catalysts at low temperature, which is advantageous in some food processing operations (Simpson 2000). For example, cold-adopted pepsins are very effective for cold renneting milk clotting because of the high activity at low reaction temperatures (Simpson 2000). Moreover, fish digestive enzymes possessing other unique properties might make them better suited as food processing aids.

Recently, the use of alkaline proteases from marine digestive organs, especially trypsin, has increased remarkably since they are both stable and active under harsh conditions, such as at temperatures of 50–60°C, high pHs, and in the presence of surfactants or oxidizing agents (Klomklao et al. 2005). Trypsin can be used for extraction of carotenoprotein from shrimp processing wastes. Cano-Lopez et al. (1987) reported that using trypsin from Atlantic cod pyloric ceca in conjunction with a chelating agent (EDTA) in the extraction medium increased the efficacy in recovering both protein and pigment from crustacean wastes. This method has facilitated the recovery of as much as 80% of astaxanthin and protein from shrimp wastes as carotenoprotein complex. Recently, Klomklao et al. (2009c) also recovered carotenoproteins from black tiger shrimp waste by using trypsin from the pyloric ceca of bluefish. The product obtained contained higher protein and pigment content than those of black tiger shrimp waste and had low contents of chitin and ash.

The enzymes recovered from fish have also been successfully used as seafood processing aids including the acceleration of fish sauce fermentation. Chaveesuk et al. (1993) reported that

the supplementation with trypsin and chymotrypsin significantly increased protein hydrolysis of fish sauce. Fish sauce prepared from herring with enzyme supplementation contained significantly more total nitrogen, soluble protein, free amino acid content, and total amino acid content, compared to fish sauce with no added enzyme (Chaveesuk et al. 1993). By supplementing minced capelin with 5–10% enzyme-rich cod pyloric ceca, a good recovery of fish sauce protein (60%) was obtained after 6 months of storage (Gildberg 2001). In addition, Klomklao et al. (2006c) reported that fish sauce prepared from sardine with spleen supplementation contained greater total nitrogen, amino nitrogen, and ammonia nitrogen contents than those without spleen supplementation throughout the fermentation. Therefore, the addition of spleen can accelerate the liquefaction of sardine for fish sauce production.

Proteolytic enzymes also show profound effects on collagen extraction. Generally, use of pepsin in combination with acid extraction increased in the yield of collagen. Nagai et al. (2002) reported that the yield of pepsin-solubilized collagen was higher (44.7%) than acid-solubilized collagen (10.7%). Nagai and Suzuki (2002) found that the collagen extracted from the outer skin of the paper nautilus was hardly solubilized in 0.5 M acetic acid. The insoluble matter was easily digested by 10% pepsin (w/v), and a large amount of collagen was obtained with 50% yield (pepsin-solubilized collagen). Collagen from the outer skin of cuttlefish (*Sepia lycidas*) was also extracted by Nagai et al. (2001). The initial extraction of the cuttlefish outer skin in acetic acid yielded only 2% of collagen (dry weight basis). With a subsequent digestion of the residue with 10% pepsin (w/v), a solubilized collagen was obtained with a yield of 35% (dry weight basis). Pepsin solubilized collagen was extracted from the skin of grass carp (*Ctenopharyngodon idella*) with a yield of 35% (dry weight basis) (Zhang et al. 2007). Recently, Nalinanon et al. (2007) studied the use of fish pepsin as processing aid to increase the yield of collagen extracted from fish skin. Addition of bigeye snapper pepsin resulted in the increased content of collagen extracted from bigeye snapper skin. The yields of collagen from bigeye snapper skin extracted for 48 hours with acid and with bigeye snapper pepsin were 5.31% and 18.74%

(dry basis), respectively. With pre-swelling in acid for 24 hours, collagen extracted with bigeye snapper pepsin for 48 hours had the yield of 19.79%, which was greater than that of collagen extracted using porcine pepsin at the same level (13.03%) (Nalinanon et al. 2007).

TRANSGLUTAMINASE

Transglutaminase (TGase; EC 2.3.2.13) is a transferase whose systematic name is protein-glutamine γ-glutamyltransferase. The enzyme catalyzes the acyl transfer reaction in which the γ-carboxyamine groups of glutamine residues in proteins, peptides, and various primary amines, act as acyl donors and primary amino groups including ε-amino groups of lysine residues, either as peptide-proteins bound or free lysine, act as the acyl acceptor (Folk 1980, Worratao and Youngsawatdigul 2005). When acceptors are ε-amino groups of lysine residues, the formation of ε-(γ-glutamyl)lysine linkages occur both intra-and intermolecularly (Folk 1980). This occurs through the exchange of the ε-amino groups of the lysine residues for the ammo-

nia at the γ-carboxyamide group of a glutamine residue in a protein molecule (Fig. 14.4). Formation of covalent cross-links between proteins is the basis of the ability of TGase to modify the physical characteristics of protein foods (Ashie and Lanier 2000). These bonds are stable and resistant to proteolysis (Worratao and Youngsawatdigul 2005). Amino acid sequence and the charge of amino acids surrounding the susceptible glutamine residue and local secondary structures affected the cross-linking capability (Folk 1980).

TGase has been widely used to improve functional properties of various food proteins (Benjakul et al. 2004a). TGase is an endogenous fish enzyme responsible for cross-linking of proteins and change textural properties of fish sol during processing, especially surimi production (Ashie and Lanier 2000). This is known to reinforce the thermal myosin gelation that occurs during surimi production by the formation of intra- and intermolecular cross-links between myosin heavy chains known as setting. This setting phenomenon, called suwari, is one of the important processes for manufacturing surimi-based products (Shahidi and Kamil 2001).
Figure 14.4. Cross-linking of proteins by transglutaminase.

Endogenous TGases from the muscle tissues of different fish species vary in properties such as different MWs, pH, and temperature optima. TGase activity has been found in muscle of red sea bream (*Pagrus major*), rainbow trout (*Oncorhynchus mykiss*), atka mackerel (*Pleurogrammus azonus*) (Muruyama et al. 1995), walleye pollock liver (*Theragra chalcogramma*) (Kumazawa et al. 1996), muscle of scallop (*Patinopecten yessoensis*), botan shrimp (*Pandalus nipponensis*), and squid (*Todarodes pacificus*) (Nozawa et al. 1997). Worratao and Yongsawatdigul (2005) demonstrated that tropical tilapia (*Oreochromis niloticus*) muscle contained high TGase activity. Generally, the optimum temperature of TGase ranged from 25°C to 55°C, depending on fish species. Nozawa et al. (1997) described TGase in fish muscle as calcium dependent. Worratao and Youngsawatdigul (2005) also reported that purified tilapia TGase had an absolute requirement for calcium ions. TGase activity increased with Ca^{2+} concentration and reached the maximum at 1.25 mM. Optimal Ca^{2+} concentrations for TGase from red sea bream liver, Japanese oyster, scallop, and pollock liver were at 0.5 mM, 25 mM, 10 mM, and 3 mM, respectively (Yasueda et al. 1994, Kumazawa et al. 1996,, Nozawa et al. 2001). It was postulated that the calcium ions induced conformational changes of the enzyme that consequently exposed the cysteine located at the active site to a substrate (Ashie and Lanier 2000). Noguchi et al. (2001) reported that the calcium ions attach to a binding site of red sea bream TGase molecule, resulting in conformational changes. Subsequently, Tyr covering the catalysis cystine (Cys) was removed. Then, the acyl donor binds with the Cys at the active site, forming an acyl-enzyme intermediate.

POLYPHENOLOXIDASE

Polyphenoloxidase (PPO, EC 1.14.18.1) is a copper enzyme (Goulart et al. 2003), whose active site contains two copper atoms, each of which is liganded to three histidine residues (Fig. 14.5) (Whitaker 1995, Kim et al. 2000). This copper pair is the site of interaction of PPO with both molecular oxygen and its phenolic substrates (Kim et al. 2000). PPO is also known as phenoloxidase (PO), polyphenolase, phenolase, tyrosinase, and cresolase (Whitaker 1995). This enzyme catalyzes the hydroxylation of monophenols to *o*-diphenols and the oxidation of *o*-diphenols to *o*-quinones. Quinones are highly reactive prod-

ucts and can polymerize spontaneously to form brown pigments (melanin), or react with amino acids and proteins that enhance the brown color produced (Fig. 14.6) (Goulart et al. 2003, Martinez-Alvarez et al. 2008). Enzyme isolated from various sources exhibited different activities depending on the substrates used. Tyr has been reported to be a natural substrate for PO activity in crustacea. Hydroxylation of Tyr leads to the formation of dihydroxyphenylalanine (DOPA) (Kim et al. 2000), which is then converted to dopaquinone and water and can be readily converted to the orange-red pigment, dopachrome (Simpson et al. 1987).
PO has been shown to play a central role in the innate immune system of crustacea (Williams et al. 2003). This enzyme is expressed from their hemocytes as its precursor, prophenoloxidase (proPO) and functions in various phases of the live organism such as sclerotization, pigmentation, wound healing on cuticles, and defense reaction (Adachi et al. 2001). PO has been detected in the hemocyte, hemolymph, cuticle, accessory gland, egg case, salivary gland, and midgut in insects (Adachi et al. 1999). In crustaceans, PO is localized in different parts. It is found on the exoskeleton, chiefly on the region of the pleopods' connection (Montero et al. 2001).

The activation of proPO in hemocyte, or hemolymph, is initiated by minute amounts of bacterial or fungal cell wall components (β-1,3-glucans, lipopolysaccharides, and peptidoglycans) and mediated by several factors including protease cascade reaction (Adachi et al. 1999, Williams et al. 2003). The serine protease that exhibits trypsin-like activity cleaves the proPO between an arginine residue and a Thr residue to yield active PO (Williams et al. 2003). The proPO of kuruma prawn homocyte was activated by SDS and methanol but not by trypsin (Adachi et al. 1999).

PPO has been found in crustaceans such as shrimp (Chen et al. 1997), lobster (Chen et al. 1991), pink shrimp (Simpson et al. 1988), white shrimp (Simpson et al. 1987), black tiger shrimp (Rolle et al. 1991), Florida prawn (Ali et al. 1994), kuruma prawn (Benjakul et al. 2005), imperial tiger prawn (Montero et al. 2001), and deep water pink shrimp (Zamorano et al. 2009). PPO is distributed in many parts of shrimps with different levels of activity (Montero et al. 2001). PO is localized in the carapace of the cephalothorax, in the caudal zone and in the cuticle of the abdomen, mainly where the cuticle segments are joined and where the cuticle is connected to the pleopods (Ogawa et al. 1984). Zamorano et al. (2009) studied the tissue distribution of PPO in deepwater pink shrimp (*Parapenaeus longirostris*) postmortem. PPO activity was highest in the carapace, followed by that in the abdomen exoskeleton, cephalotorax, pleopods, and telson. No PPO activity was found in the abdominal muscle and in the pereopods and maxillipeds. Storage of whole shrimps and of the different organs showed that melanosis required the presence of the cephalotorax to be initiated, indicating that its development depends on other factions in addition to the PPO levels.

Figure 14.5. Coordination of copper to six histidine residues in active site of polyphenoloxidase.

FACTORS AFFECTING PPO ACTIVITY

PPO differs in isoforms, latency, catalytic behavior, MW, specificity, and hydrophobicity. In addition, optimum pH, thermal
Figure 14.6. Enzymatic oxidation induced by PPO.

stability, and kinetic parameters can vary with species, body part, and so forth. (Montero et al. 2001).

Temperature

PPO shows different optimal temperatures among various animals or species. Montero et al. (2001) reported that the optimum temperature of PPO from imperial tiger prawn was between 40°C and 60°C. Thermal stability was considerably reduced when the enzyme extract was subjected to temperatures up to 35°C. Rolle et al. (1991) observed that the PPO from Taiwanese tiger shrimp (*Penaeus monodon*) exhibited a temperature optimum of 45°C and showed stability over the temperature range of 30–35°C. The optimum temperature for PPO from the imperial tiger prawn carapace was between 40°C and 60°C; however, thermal stability was greatest at temperatures below 35°C (Montero et al. 2001). Zamorano et al. (2009) found that the maximal activity of PPO of deepwater pink shrimp was observed in the 15–60°C range. Benjakul et al. (2005) reported that the PO from the kuruma prawn cephalothorax showed the maximum activity at 35°C and the enzyme was unstable at temperatures above 50°C.

The determination of the temperature/time profiles required to activate the proenzyme and to prevent melanosis and improve postprocessing quality and acceptability is a means to regulate or control the quality of crustaceans deteriorated by melanosis (Williams et al. 2003).

pH

The optimum pH depends largely on the physiological pH in which the enzyme activity occurs in nature. For example, the pH of the carapace of the cephalothorax was 7.16, while in the abdominal cuticle, it was 8.76. Therefore, the enzymes would probably present different optimum pH characteristics, depending on the locus of extraction. Montero et al. (2001) reported that high PPO activity occurred at pH 5 and 8 in *Penaeus japonicus*. PPO from deepwater pink shrimp had the highest activity at pH 4.5 and was most stable at pH 4.5 and 9.0. Benjakul et al. (2005) found that PO from kuruma prawn cephalotorax showed the maximal activity at pH 6.5 and it was stable in a wide pH range of 3–10. The stability of the PO was very different depending on a number of factors such as temperatures, pH, substrate used, ionic strength, buffer system, and time of incubation (Kim et al.

Table 14.5. Characteristic of polyphenoloxidase from Crustaceans

Source	MW (kDa)	pH Optimum	pH Stability	Temperature Optimum (°C)	Reference
Kuruma prawn	160	6.5	3–10	35	Benjakul et al. (2005)
Imperial tiger prawn	–	5–8	Basic pH	40–60	Montero et al. (2001)
Deepwater pink shrimp	200	4.5	4.5–9.0	15–60	Zamorano et al. (2009)
Clam	76.9	7.0	-	40	Cong et al. (2005)
White shrimp	30	6.5–7.5	8.0	45	Simpson et al. (1987)
Lobster	–	6.5	7.5	30	Opoku-Gyamfua et al. (1992)
Crab	64.5	6.0	–	40	Liu et al. (2006)

2000). The characteristics of PPO from different crustaceans are summarized in Table 14.5.

Activators/Inhibitors

One characteristic of PPO is its ability to exist in an inactive or latent state. PPO can be released from latency by several agents or treatments such as incubation with ammonium sulfate, anionic detergents, carboxymethylcellulose, urea, guanidine salts, short-time acid or base treatment or a limited proteolysis (Whitaker 1995), and alcohol (methanol) (Adachi et al. 1999).

Several factors have been reported to influence PPO activity. They include: (a) a proenzyme, (b) a PPO-bound inhibitor, and (c) a conformation change (Gauillard and Richard-Forget 1997). Chazarra et al. (1997) reported that the presence of SDS in the assay medium provokes a conformation change in the latent iceberg lettuce PPO, leading to an increase in PPO activity with increasing concentration. Adachi et al. (1999) and Mazzafera and Robinson (2000) also found that proPPO from kuruma prawn was activated by SDS. Some ion or salts affect the PPO activity. $MnSO_4$ and $CaCl_2$ enhanced PPO activity (Adachi et al. 1999). Kim et al. (2000) observed that the activity was increased by addition of 1 mM Mg^{2+}, K^+, or Cu^{2+}. However, the activity of PPO was dependent on the concentrations of divalent cations (Adachi et al. 1999). Adachi et al. (1999) reported that the highest activity of PPO from kuruma prawn was obtained at a concentration of 50 mM for both Mg^{2+} and Ca^{2+}. Ascorbic acid, cysteine, glutathione, thiourea, and hexyl-resorcinol were demonstrated to control enzymatic browning induced by PPO (Guerrero-Beltran et al. 2005). Benjakul et al. (2005) reported that phenylthiourea, a copper-chelating agent, and cysteine exhibited inhibitory effects against PPO from kuruma prawn. Total inhibition of the extract from imperial tiger prawn was achieved with ascorbic acid and citric acid at pH 3.0 (Montero et al. 2001). Nirmal and Benjakul (2009a) found that ferulic acid and oxygenated ferulic acid inhibited PPO from Pacific white shrimp, and ferulic acid was the more effective inhibitor than oxygenated ferulic acid. Recently, Nirmal and Benjakul (2009b) reported that catechin showed inhibitory ac-

tivity toward PPO of Pacific white shrimp in a dose-dependent manner.

MELANOSIS

Melanosis is a process that is triggered by the oxidation of phenols to quinones induced by PPO or PO (Montero et al. 2001). PO is responsible for a discoloration in crustacean species such as lobster, shrimp, and crab. The postmortem dark discoloration in crustaceans, called melanosis or blackspot, connotes spoilage (Kim et al. 2000). Melanosis reduces the market value of these foods and causes large financial losses to the food industry (Williams et al. 2003).

Melanosis or blackspot appears very frequently during postmortem storage of crustacea prior to the onset of spoilage. Melanosis starts in refrigerated crustaceans within a few hours of capture, and the susceptibility is often greater in autumn and winter, coinciding with molting and lower food availability (Montero et al. 2001). Marine crustaceans form the black spots on their tail, cephalothoraxes, and podites during storage (Adachi et al. 1999). In chilled prawns and shrimps, the melanosis reaction begins from the head region and spreads to the tail (Simpson et al. 1987), and the rate of spread of melanosis differs among various species. This could be related to differences in levels of substrate or levels of enzyme concentration or enzymatic activity in each species (Simpson et al. 1987). Pink shrimp PPO oxidized DOPA 1.8-fold more rapidly than white shrimp PPO. Pink shrimp carapace has relatively higher levels of free Tyr and phenylalanine, the natural substrates of melanosis, than white shrimp carapace (Rolle et al. 1991). The enzymatic oxidation to form melanin is associated with the stages of molting cycle, sex, and occurrence of injury or trauma (Ogawa et al. 1984). To prevent or retard melanosis, several PPO inhibitors including reducing agents or antioxidants inhibitors such as sulfiting agent, cysteine, acidulants, and metal ion chelators have been used. Because of the susceptibility of certain individuals to the residual level of sulfiting agents commonly used for melanosis prevention in crustaceans, natural additives such as plant phenols have been used to reduce melanosis formation in
| Control | SMS | 0.05% Catechin | 0.1% Catechin |

crustaceans during postmortem storage or handling. Whole Pacific white shrimp treated with catechin solution (0.05% or 0.1%) kept in ice for 10 days retarded melanosis in comparison with the control and those treated with 1.25% sodium metabisulfite (Nirmal and Benjakul 2009b) (Fig. 14.7).

TRIMETHYLAMINE-*N*-OXIDE DEMETHYLASE

TMAOase (EC 4.1.2.32) catalyzes the conversion of trimethylamine oxide (TMAO) to dimethylamine (DMA) and formaldehyde (FA) (Gill and Paulson 1982). TMAOase is one of the important enzymes in fish exhibiting an adverse effect on fish quality. TMAOase has been found at different degrees in various fish species. The inhibition or lowering of TMAOase activity in the postharvest animal could be an effective approach to maintain fish quality.

DISTRIBUTION OF TMAOASE

Although TMAO is distributed among all kinds of marine fish and invertebrates, and in some fresh water fish, TMAOase activity has been identified in only 30 species of marine fish belonging to 10 families and 8 species of invertebrates, mainly mollusk (Sikorski and Kostuch 1982). Accumulation of DMA and FA has been described in species belonging to Gadidae, Merluccidae, and Myctophidae (Sikorski and Kostuch 1982). Among the fish, Gadiform (families Gadidae and Merluccidae) is a group of fish with high TMAOase activity (Sotelo and Rehein 2000).

The level of TMAOase in a particular species and tissue exhibits variations (Rehbein and Schreiber 1984) and seems to be influenced by factors such as gender, maturation stage, temperature of the habitat, and feeding status, or size (Sotelo and Rehein 2000).

Depending on the source of the enzyme, the activity may be located in the soluble fraction or in the particulate matter of homogenates of organs or tissues (Sotelo and Rehein 2000). The organs and tissues including viscera and skin contain TMAOase. Harada (1975) isolated TMAOase from the liver of lizardfish (*Saurida tumbil*). Distribution of TMAOase in various inter-

nal organs of lizardfish (*Saurida micropectoralis*) were studied (Benjakul et al. 2004b). Rey-Mansilla et al. (2002) studied the activities of TMAOase from several internal organs of hake (kidney, spleen, liver, heart, bile, and gallbladder). It was found that kidney and spleen showed the highest activities while liver, heart, bile, and gallbladder activities were much lower. Moreover, TMAOase has been found in muscle of some fish species, such as red hake (Phillipy and Hultin 1993) and walleye pollack (Kimura et al. 2000).

PURIFICATION AND CHARACTERIZATION OF TMAOASE

Harada (1975) partially purified TMAOase from liver of lizardfish (*Saurida tumbil*) and found that the enzyme had an optimum pH of 5.0 and required methylene blue for activation. Tomioka et al. (1974) found that TMAOase activity from pyloric ceca of Alaska pollack was stimulated by Fe^{2+}, L-ascorbic acid, flavin mononucleotide (FMN) and inhibited by Fe^{3+}, Cu^{2+}, EDTA, trimethylamine, and choline. TMAOase associated with Alaska pollack myofibrils has been characterized (Kimura et al. 2000). The enzyme requires cofactors for full activity. The system of nicotinamide adenine dinucleotide and FMN requires anaerobic conditions while the system of iron and cysteine and/or ascorbate functions in the presence or absence of oxygen (Parkin and Hultin 1986). Benjakul et al. (2003b) purified TMAOase from lizardfish (*Saurida micropectoralis*) kidney by acidification followed by DEAE–cellulose column chromatography, in which a purification fold of 82 with a yield of 65.4% were obtained. The molecular mass of the partially purified enzyme was estimated to be 128 kDa based on activity staining. Optimum pH and temperature were 7.0 and 50°C, respectively. The activation energy was calculated to be 30.5 kJ $mol^{-1}K^{-1}$. Combined cofactors ($FeCl_2$, ascorbate, and cysteine) were required for full activation. Fe^{2+} exhibited a higher stimulating effect on TMAOase activity than Fe^{3+}. At concentrations less than 2 mM, ascorbate was more stimulatory of TMAOase activity than cysteine. TMAOase was tolerant to salt at concentrations up to 0.5 M. The enzyme had a K_m of 16.24 mM and V_{max} of 0.35 μmol/min, and was able to convert TMAO to DMA and FA. Leelapongwattana et al. (2008a) partially purified TMAOase from lizardfish

kidney by heat treatment, ammonium sulfate precipitation, and a series of chromatographies including Sephacryl S-300 and DEAE–cellulose. The addition of partially purified TMAOase from lizardfish kidney to haddock natural actomyosin in the presence of cofactors ($FeCl_2$, ascorbate, and cysteine) accelerated formaldehyde formation throughout the storage either at $4°C$ or $-10°C$.

PREVENTION OF TMAOASE ACTIVITY

TMAOase inhibition has been focused on preventing loss of quality in frozen fish, especially in some species such as cod. The inhibition of the TMAO demethylation can be achieved using several inhibitors. Most of them are general inhibitors of redox reactions, being strong oxidants, such as H_2O_2, which inhibits the reaction (Phillipy and Hultin 1993). The presence of oxygen or oxidants can promote inhibition of enzymatic TMAO breakdown in frozen red hake (Racicot et al. 1984). Iodoacetamide, cyanide, and azide have been shown to inhibit TMAOase activity (Sotelo and Rehein 2000); while sodium citrate and H_2O_2 have been found to slow down the rate of DMA and FA formation in frozen gadoid mince (Racicot et al. 1984). Treating Alaska pollack fillets with sodium citrate and sodium pyruvate before freezing resulted in a less texture toughening (Krueger and Fennema 1989). Furthermore, the addition of 0.5% alginate could lower the DMA and FA formation in minced fillet of mackerel stored at $-20°C$ for 2 months (Ayyad and Aboel-Niel 1991).

Apart from reducing protein denaturation, cryoprotectants have also been reported to prevent FA formation. Sotelo and Mackie (1993) found a protective role of different cryoprotectants (amino acids and sugars) in preventing FA-promoted aggregation of bovine serum albumin during frozen storage. The binding of FA during frozen storage was dependent on protein rearrangements in the way that reactive groups become available. The constraints of cryostabilizers on molecular diffusion reduced the exposure of these groups (Herrera et al. 1999). Herrera et al. (2000) also reported that the addition of maltodextrins to minced blue whiting muscle inhibited FA production during storage at $-10°C$ and $-20°C$. Sucrose, however, was effective only at $-20°C$. Herrera et al. (2002) studied the effects of various cryostabilizers on inhibiting FA production in frozen-stored minced blue whiting muscle. Several maltodextrins (dextrose equivalent 9, 12, 18, and 28) or sucrose minimized the decrease in protein solubility during storage at $-10°C$ and $-20°C$. These effects were greater at $-20°C$, and DE 18 maltodextrin seemed to be the most effective treatment at both temperatures. Conversely, sucrose was as effective as maltodextrins at $-20°C$, but showed hardly any effect at $-10°C$. A high correlation was found between the effectiveness of cryostabilizers in preventing protein alterations and their effectiveness in inhibiting FA production, particularly at $-10°C$. In addition, a sigmoidal relationship between protein solubility and FA content was found at this temperature, which supports the hypothesis of the cooperative nature of the effect of FA on protein alterations (Herrera et al. 2002).

Addition of TMAOase inhibitors could be a means to retard the loss in textural properties of some fish species associated with FA formation. Leelapongwattana et al. (2008b) reported that sodium citrate and pyrophosphate could inhibit TMAOase activity from lizardfish muscle in a concentration dependent manner, most likely due to their chelating property. Sodium alginate is a hydrocolloid possessing inhibitory activity toward TMAOase. During the storage of lizardfish mince at $-20°C$ for 24 weeks, the addition of 0.5% sodium alginate and 0.3% pyrophosphate in combination with 4% sucrose and 4% sorbitol as the cryoprotectants slowed down TMAOase activities and lowered the formation of DMA and FA. The addition of TMAOase inhibitor (0.3% pyrophosphate and 0.5% alginate) in haddock mince containing TMAOase retarded FA formation throughout storage at $-10°C$ for 6 weeks. On the other hand, antioxidants (250 mg ascorbic acid/kg and 250 mg tocopherol/kg) induced FA formation (Leelapongwattana et al. 2008a, 2008b).

Moreover, TMAO has also been found to exert a protective role over proteins. It has been shown that TMAO stabilizes fish muscle proteins and some enzymes during the frozen storage (LeBlanc and LeBlanc 1989).

LIPASE

Lipases (triacylglycerol acylhydrolases; EC 3.1.1.3) constitute a group of enzymes defined as carboxylesterases that catalyze the hydrolysis (and synthesis) of long-chain acyl-glycerols at the lipid–water interface (Cherif and Gargouri 2009). The two main categories in which lipase-catalyzed reactions may be classified are given in Figure 14.8.

From Figure 14.8, the last three reactions are often grouped together into a single term, namely, transesterification.

Lipases are important because of the role they play in the postmortem quality deterioration of seafood (and other foodstuffs) during handling, chilled, and frozen storage. Lipases are finding increasing uses as food and others industrial processing aids (Aryee et al. 2007). Compared with other hydrolytic enzymes (e.g., proteases and carbohydrases), lipases are relative less well studied and in this regard, lipases from aquatic animals are even less well-known versus their counterparts from mammalian, plant, and microbial sources (Aryee et al. 2007). The presence of a lipolytic activity and partial characterization of a lipase in marine organisms have been reported in few studies. The pH and temperature optima of most lipases lie between 7 and 9 and $35°C$ and $60°C$, respectively. Lipases are active over a very wide temperature range of $-20°C$ to $65°C$, but the more usual range is $30–45°C$ (Shahidi and Kamil 2001).

The presence of a lipase activity has been described for some fish and aquatic organisms. Mukundan et al. (1985) described the purification of a lipase from the hepatopancreas of oil sardine using anion-exchange chromatography and gel filtration. The glycosylated enzyme (6.1% carbohydrate) showed a MW of 54–57 kDa (by gel filtration), was marginally activated by approximately 1 mM Ca^{2+}, was completely inhibited by approximately 1 mM F^-, and hydrolyzed tributyrin most efficiently among C2–C18 monoacid triglycerides (TGs). Sardine lipase exhibited optimum activity against tributyrin at pH 8–8.5 and
(A) Hydrolysis:

$$RCOOR' + H_2O \quad\quad \leftrightarrow \quad\quad RCOOH + R'OH$$

(B) Synthesis:

Reactions under this category can be further separated:

(a) Esterification

$$RCOOH + R'OH \quad\quad \leftrightarrow \quad\quad RCOOR' + H_2O$$

(b) Interesterification

$$RCOOR' + R''COOR^{\bullet} \quad\quad \leftrightarrow \quad\quad RCOOR^{\bullet} + R''COOR'$$

(c) Alcoholysis

$$RCOOR' + R''OH \quad\quad \leftrightarrow \quad\quad RCOOR'' + R'OH$$

(d) Acidolysis

$$RCOOR' + R''COOH \quad\quad \leftrightarrow \quad\quad R''COOR' + RCOOH$$
Figure 14.8. Lipase reactions.

37°C. The enzyme was stable up to 45°C for 15 minutes and in the pH range 5–9.5 after a 1-hour incubation period. A lipase from the hepatopancreas of red sea bream was purified and characterized by Iijima et al. (1998). The enzyme was extracted by a combination of anion exchange, hydrophobic interaction, and gel filtration. The MW of the lipase was 64 kDa and the enzyme exhibited the maximal activity at pH 7–9. The lipolytic activity of the red sea bream enzyme is Ca^{2+} independent. Lipase was purified from tilapia intestine using ion exchange, chromatofocusing, and gel filtration chromatography techniques (Taniguchi et al. 2001). The temperature optimum was 35°C and it was stable below 40°C. The pH stability fell within the relatively narrow range of 6.5–8.5 and the highest activity was at pH 7.5, typical of corresponding mammalian lipases and those from other fish species. The inclusion of bile salts caused an approximate 9-fold increase in the enzyme activity. The tilapia lipase's MW of 46 kDa, pH of 4.9 and efficient hydrolysis of soybean and coconut oils are characteristics similar to mammalian lipase. A lipase was partially purified from the viscera of grey mullet by ammonium sulfate fractionation, ultrafiltration, and cholate-Sepharose affinity chromatography (Aryee et al. 2007). Optimum activity against *p*-nitrophenyl palmitate was displayed at pH 8. The temperature optimum was 50°C. Grey mullet lipase is completely stable in several water-immiscible organic solvents, suggesting that it may have potential applications for synthesis reactions in organic media.

Recently, Cherif and Gargouri (2009) purified crab digestive lipase from crab hepatopancreas by heat treatment, DEAE–cellulose, ammonium sulfate precipitation, S-200, Mono-Q, and S-200. The enzyme had a molecular mass of 65 kDa. The maximum activity of crab lipase appeared at pH 8. Lipase activity was compatible with the presence of organic solvents, except for butanol. Furthermore, the hydrolysis was found to be specifically dependent on the presence of Ca^{2+} to trigger the hydrolysis of tributyrin emulsion.

FISH LIPASE APPLICATIONS

Lipases have been widely used for biotechnological applications in detergents, and dairy and textile industries, production of surfactants and oil processing. Recently, lipases have received considerable attention with regard to the preparation of enantiomerically pure pharmaceuticals, since they have a number of unique characteristics: substrate specificity, regiospecificity, and chiral selectivity (Cherif and Gargouri 2009). Because of their high affinity for long chain fatty acids, specificity for particular fatty acids and regiospecificity (Kurtovic et al. 2009), fish digestive lipases may find applications in the synthesis of structured lipids. Using lipases, TGs could be enriched with certain beneficial fatty acids, like eicosapentaenoic acid or docosahexaenoic acid at a specific position along the glycerol backbone. Enzymatic synthesis of modified lipids using lipases could be economically more attractive than chemical synthesis because of the lower energy requirements and specificity. In addition, long-chain PUFAs are highly labile and lipase-catalyzed lipid modifications could prevent detrimental oxidation and *cis-trans* isomerization processes. Lipases have the important physiological role of preparing the fatty acids of water-insoluble triacylglycerols (TAG) for absorption into and transport through membranes by converting the TAG to the more polar diacylglycerols, monoacylglycerols, free-fatty acids, and glycerol (Shahidi and Kamil 2001). Marine lipases are likely to have advantages over their microbial or mammalian counterparts because they may operate more efficiently at lower temperatures. Termination of enzymatic reactions could be achieved by smaller changes in temperature as marine lipases often have lower temperature optima and stabilities than lipases from other sources. The lipases do not require potentially hazardous high or low pH media in contrast to the requirements of many chemically driven reactions. Fish digestive lipases could also carry out lipid interesterification reactions (e.g., transesterification) with minimal or no by-products, a problem often encountered in chemical

transformations. The screening for fish digestive lipases with alkaline pH optima would allow the identification of suitable enzymes for use in cleaners and household detergents.

Some fish digestive lipases are stereospecific as well as enantiospecific and these features could allow the lipases to be used in the synthesis of specialty pharmaceuticals and agrochemicals where enantiomerically pure products are desired. Specialty esters for personal care products and environmentally safe surfactants for applications in detergents and as food emulsions may also await the application of fish digestive lipases (Kurtovic et al. 2009).

Meat, Poultry and Seafoods

15
Biochemistry of Raw Meat and Poultry

Fidel Toldrá and Milagro Reig

Abstract: The consumers' concern for safety and health is driving the consumption patterns in accordance to meat composition, especially for some key substances. In addition, a significant percentage of meat is used as raw material for further processing into different products such as cooked, fermented, and dry-cured meats and one of the most relevant problems of the meat industry is that genetics, age and sex, intensive or extensive production systems, type of feeding and slaughter procedures including preslaughter handling,

stunning methods, and postmortem treatment have an influence on important biochemical traits with a direct effect on the meat quality and its aptitude as raw material. All these factors are described in this chapter.

BACKGROUND INFORMATION

In recent years, there has been a decline in consumption of beef, accompanied by a slight increase in pork and an increased demand for chicken. There are many reasons behind these changes including the consumer concern for safety and health, changes in demographic characteristics, changes in consumer lifestyles, availability and convenience, price, and so on (Resurreccion 2003). The quality perception of beef changes depending on the country. So, Americans are concerned with cholesterol, calorie content, artificial ingredients, convenience characteristics, and price (Resurreccion 2003). In the United States, this changing demand has influenced the other meat markets. Beef has been gradually losing market share to pork and, especially, chicken (Grunert 1997).

But a significant percentage of meat is used as raw material for further processing into different products such as cooked, fermented, and dry-cured meats. Some of the most well-known meat products are bacon, cooked ham, fermented and dry-fermented sausages, and dry-cured ham (Flores and Toldrá 1993, Toldrá 2002).

The processing meat industry faces various problems, but one of the most important is the variability in the quality of meat as a raw material. Genetics, age and sex, intensive or extensive production systems, type of feeding and slaughter procedures including pre-slaughter handling, stunning methods, and postmortem treatment have an influence on important biochemical traits with a direct effect on the meat quality and its aptitude as raw material.

STRUCTURE OF MUSCLE

A good knowledge of the structure of muscle is essential for the use of muscle as meat. The structure is important for the properties of the muscle, and its changes during postmortem events influence the quality properties of the meat.

Muscle has different colors within the range of white to red, depending on the proportion of fibers. There are different classifications for fibers. On the basis of color, they can be classed as red, white, or intermediate (Moody and Cassens 1968): (1) red fibers are characterized by a higher content of myoglobin and higher numbers of capillaries and mitochondria, and they exhibit oxidative metabolism; (2) white fibers contain low amounts of myoglobin and exhibit glycolytic metabolism; and (3) intermediate fibers exhibit intermediate properties. Red muscles contain a high proportion of red fibers and are mostly related to locomotion, while white muscles contain a higher proportion of white fibers and are engaged in support tasks (Urich 1994). Other classifications are based on the speed of contraction (Pearson and Young 1989): Type I for slow-twitch oxidative fibers, type IIA for fast-twitch oxidative fibers, and IIB for fast-twitch glycolytic fibers.

The skeletal muscle contains a great number of fibers. Each fiber, which is surrounded by connective tissue, contains around 1000 myofibrils, all of them arranged in a parallel way and responsible for contraction and relaxation. They are embedded in a liquid known as sarcoplasm, which contains the sarcoplasmic (water-soluble) proteins. Each myofibril contains clear dark lines, known as Z-lines, regularly located along the myofibril (see Fig. 15.1). The distance between two consecutive Z-lines is

known as a sarcomere. In addition, myofibrils contain thick and thin filaments, partly overlapped and giving rise to alternating dark (A band) and light (I band) areas. The thin filaments extend into the Z-line that serves as linkage between consecutive sarcomeres. All these filaments are composed of proteins known as myofibrillar proteins.

Muscle, fat, bones, and skin constitute the main components of carcasses; muscle is the major compound and is, furthermore, associated to the term of meat. The average percentage of muscle in relation to live weight varies depending on the species, degree of fatness, and dressing method: 35% for beef, 32% for veal, 36% for pork, 25% for lamb, 50% for turkey, and 39% for broiler chicken. The muscle to bone ratio is also an important parameter representative of muscling: 3.5 for beef, 2.1 for veal, 4.0 for pork, 2.5 for lamb, 2.9 for turkey, and 1.8 for poultry (Kauffman 2001).

MUSCLE COMPOSITION

Essentially, meat is basically composed of water, protein, lipids, minerals, and carbohydrates. Lean muscle tissue contains approximately 72–74% moisture, 20–22% protein, 3–5% fat, 1% ash, and 0.5% of carbohydrate. An example of typical pork meat composition is shown in Table 15.1. These proportions are largely variable, especially in the lipid content, which depends on species, amount of fattening, inclusion of the adipose tissue, and so on. There is an inverse relationship between the percentages of protein and moisture and the percentage of fat so that

Figure 15.1. Structure of a myofibril with details of main filaments in the sarcomere.

Table 15.1. Example of the Approximate Composition of Pork Muscle *Longissimus Dorsi*. Expressed as Means and Standard Deviation (SD)

	Units	Mean	SD
Gross composition			
Moisture	g/100g	74.5	0.5
Protein	g/100g	21.4	2.1
Lipid	g/100g	2.7	0.3
Carbohydrate	g/100g	0.5	0.1
Ash	g/100g	0.9	0.1
Proteins			
Myofibrillar	g/100g	9.5	0.8
Sarcoplasmic	g/100g	9.1	0.6
Connective	g/100g	3.0	0.4
Lipids			
Phospholipids	g/100g	0.586	0.040
Triglycerides	g/100g	2.12	0.22
Free fatty acids	g/100g	0.025	0.005
Some minor compounds			
Cholesterol	mg/100g	46.1	6.1
Haem content	mg/100g	400	30
Dipeptides	mg/100g	347.6	35.6
Free amino acids	mg/100g	90.2	5.8

Table 15.2. Type, Localization and Main Role of Major Muscle Proteins

Cellular Localization	Main Proteins	Main Role in Muscle
Myofibrillar	Myosin and actin	Cytoskeletal proteins providing support to the myofibril and responsible for contraction–relaxation of the muscle.
	Tropomyosin	Regulatory protein associated to troponins than cause its movement toward the F-actin helix to permit contraction.
	Troponins T, C, I	Regulatory proteins. Tn-T binds to tropomyosin, Tn-C binds Ca^{2+} and initiates the contractile process and Tn-I inhibits the actin–myosin interaction in conjunction with tropomyosin and Tn-T and Tn-C.
	Titin and nebulin	Large proteins located between Z-lines and thin filaments. They provide myofibrils with resistance and elasticity.
	α-, β-, γ-, and eu-actinin	Proteins regulating the physical state of actin. α-actinin acts as a cementing substance in the Z-line. γ-actinin inhibits the polymerization of actin at the nucleation step. β-actinin is located at the free end of actin filaments, preventing them to bind each other. Eu-actinin interacts with both actin and α-actinin.
	Filamin, synemin, vinculin, zeugmatin, Z-nin, C, H, X, F, I proteins	Proteins located in the Z-line that contribute to its high density.
	Desmin	Protein that links adjacent myofibrils through Z-lines.
	Myomesin, creatine kinase and M-protein	Proteins located in the center of the sarcomere forming part of the M-line.
Sarcoplasm	Mitochondrial enzymes	Enzymes involved in the respiratory chain.
	Lysosomal enzymes	Digestive hydrolases very active at acid pH (cathepsins, lipase, phospholipase, peptidases, glucohydrolases, etc.).
	Other cytosolic enzymes	Neutral proteases, lipases, glucohydrolases, ATPases, etc.
	Myoglobin	Natural pigment of meat.
	Hemoglobin	Protein present from remaining blood within the muscle.
Connective tissue	Collagen	Protein giving support, strength, and shape to the fibers,
	Elastin	Protein that gives elasticity to tissues like capillaries, nerves, tendons, etc.

meats with high content of fat have lower content of moisture and proteins. A brief description of proteins and lipids as major components of meat is given later.

MUSCLE PROTEINS

Proteins constitute the major compounds in the muscle, approximately 15–22%, and have important roles for the structure, normal function, and integrity of the muscle. Proteins experience important changes during the conversion of muscle to meat that mainly affect tenderness; and additional changes occur during further processing, through the generation of peptides and free amino acids as a result of the proteolytic enzymatic chain. There are three main groups of proteins in the muscle (see Table 15.2): myofibrillar proteins, sarcoplasmic proteins, and connective tissue proteins.

Myofibrillar Proteins

These proteins are responsible for the basic myofibrillar structure, and thus they contribute to the continuity and strength of the muscle fibers. They are soluble in high ionic strength buffers, and the most important of them are listed in Table 15.2. Myosin and actin are by far the most abundant and form part of the structural backbone of the myofibril. Tropomyosin and troponins C, T, and I are considered as regulatory proteins because they play an important role in muscle contraction and relaxation (Pearson 1987). There are many proteins in the Z-line region (although in a low percentage) that serve as bridges between the thin filaments of adjacent sarcomeres. Titin and nebulin are two very large proteins, present in a significant proportion, that are located in the void space between the filaments and the Z-line and contribute to the integrity of the muscle cells (Robson et al. 1997). Desmin is located on the external area of the Z-line and connects adjacent myofibrils at the level of the Z-line.

Sarcoplasmic Proteins

These are water-soluble proteins, comprising about 30–35% of the total protein in muscle. Sarcoplasmic proteins contain a high diversity of proteins (summarized in Table 15.2), mainly

metabolic enzymes (mitochondrial, lysosomal, microsomal, nuclear, or free in the cytosol) and myoglobin. Some of these enzymes play a very important role in postmortem meat and during further processing, as described in Chapter 16. Minor amounts of hemoglobin may be found in the muscle if blood has not been drained properly. Myoglobin is the main sarcoplasmic protein, responsible for the red color of meat as well as the typical pink color of drippings. The amount of myoglobin depends on many factors. Red fibers contain higher amounts of myoglobin than white fibers. The species is very important, and thus beef and lamb contain more myoglobin than pork and poultry. For a given species, the myoglobin content in the muscle increases with the age of the animal.

Connective Tissue Proteins

Collagen, reticulin, and elastin constitute the main stromal proteins in connective tissue. There are several types (I–V) of collagen containing different polypeptide chains (up to ten α-chains). Type I collagen is the major component of the epimysium and perimysium that surround the muscles. Types III, IV, and V collagen are found in the endomysium, which provides support to the muscle fiber (Eskin 1990). There are a high number of cross-linkages in the collagen fibers that increase with age, and this is why meat tougher in older animals. Elastin is found in lower amounts, usually in capillaries, tendons, nerves, and ligaments.

Enzymes

Muscle contains a large number of enzymes, mainly peptidases like calpains, cathepsins, proteasome, tri- and dipeptidylpeptidases, aminopeptidases, carboxypeptidases, and dipeptidases, but also lipases, glycohydrolase, nucleotidases, and so on (Toldrá 2007). All these enzymes have a special relevance for meat processing and they are covered in-depth in Chapter 16.

Non-protein Compounds

Free Amino Acids

The action of muscle aminopeptidases contributes to the generation of free amino acids in living muscle. An example of the typical content of free amino acids, at less than 45 minutes postmortem, in glycolytic and oxidative porcine muscles is shown in Table 15.3. It can be observed that most of the amino acids are present in significantly higher amounts in the oxidative muscle (Aristoy and Toldrá 1998). The free amino acid content is relatively low just postmortem, but it is substantially increased during postmortem storage due to the action of the proteolytic chain, which is very active and stable during meat aging.

Dipeptides

Muscle contains three natural dipeptides: carnosine (β-alanyl-L-histidine), anserine (β-alanyl-L-1-methylhistidine), and balenine (β-alanyl-L-3-methylhistidine). These dipeptides perform some physiological functions in muscle, for example, as buffers, an-

Table 15.3. Example of the Composition in Free Amino Acids (Expressed as mg/100g of Muscle) of the Glycolytic Muscle *Longissimus Dorsi* and Oxidative Muscle *Trapezius*.

Amino Acids	Muscle Longissimus dorsi	Muscle Trapezius
Essential		
Histidine	2.90	4.12
Threonine	2.86	4.30
Valine	2.78	2.09
Methionine	0.90	1.01
Isoleucine	1.52	1.11
Leucine	2.43	1.82
Phenylalanine	1.51	1.25
Lysine	2.57	0.22
Nonessential		
Aspartic acid	0.39	0.74
Glutamic acid	2.03	5.97
Serine	2.02	4.43
Asparagine	0.91	1.63
Glycine	6.01	12.48
Glutamine	38.88	161.81
Alanine	11.29	26.17
Arginine	5.19	5.51
Proline	2.83	4.45
Tyrosine	2.11	1.63
Ornithine	0.83	0.83

Source: Aristoy and Toldrá 1998.

tioxidants, neurotransmitters, and modulators of enzyme action (Chan and Decker 1994, Gianelli et al. 2000). Dipeptide content is especially higher in muscles with glycolytic metabolism (see Table 15.4), but it varies with the animal species, age, and diet (Aristoy and Toldrá 1998, Aristoy et al. 2004). Beef and pork have a higher content of carnosine and are lower in anserine, lamb has similar amounts of carnosine and anserine, and poultry is very rich in anserine (see Table 15.3). Balenine is present in minor amounts in pork muscle but at very low concentrations in other animal muscle, except in marine mammalians such as dolphins and whales (Aristoy and Toldrá 2004).

Muscle and Adipose Tissue Lipids

Skeletal muscle contains a variable amount of lipids, between 1% and 13%. Lipid content mainly depends on the degree of fattening and the amount of adipose tissue. Lipids can be found within the muscle (intramuscular), between muscles (intermuscular), and in adipose tissue. Intramuscular lipids are mainly composed of triacylglycerols, which are stored in fat cells, and phospholipids, which are located in cell membranes. The amount of cholesterol in lean meat is around 50–70 mg/100 g. Intermuscular and adipose tissue lipids are mainly composed of triacylglycerols and small amounts of cholesterol, around 40–60 mg/100g (Toldrá and Flores 2004).

Table 15.4. Example of the Composition in Dipeptides (Expressed as mg/100g of Muscle) of the Porcine Glycolytic Muscle *Longissimus Dors*i and Oxidative Muscle *Trapezius*.

	Carnosine	Anserine
Effect of muscle metabolism		
Glycolytic *(muscle Longissimus dorsi)*	313	14.6
Oxidative *(muscle. Trapezius)*	181.0	10.7
Animal species		
Pork (loin)	313.0	14.5

Lamb (neck)	94.2	119.5
Chicken (pectoral)	180.0	772.2

Source: Aristoy and Toldrá 1998, Aristoy and Toldrá 2004.

Triacylglycerols

Triacylglycerols are the major constituents of fat, as shown in Table 15.1. The fatty acid content mainly depends on age, production system, type of feed, and environment (Toldrá et al. 1996b). Monogastric animals such as swine and poultry tend to reflect the fatty acid composition of the feed in their fat. In the case of ruminants, the nutrients and fatty acid composition are somehow standardized due to biohydrogenation by the microbial population of the rumen (Jakobsen 1999). The properties of the fat will depend on its fatty acid composition. A great percentage of the triacylglycerols are esterified to saturated and monounsaturated fatty acids (see neutral muscle fraction and adipose tissue data in Table 15.5). When triacylglycerols are rich in polyunsaturated fatty acids (PUFA) such as linoleic and linolenic acids, fats tend to be softer and prone to oxidation. These fats may even have an oily appearance when kept at room temperature.

Phospholipids

These compounds are present in cell membranes, and although present in minor amounts (see Table 15.1), they have a strong relevance to flavor development due to their relatively high proportion of PUFA (see polar fraction in Table 15.5). Major constituents are phosphatidylcholine (lecithin) and phosphatidylethanolamine. The phospholipid content may vary depending on the genetic type of the animal and the anatomical location of the muscle (Hernández et al. 1998, Armero et al. 2002). For instance, red oxidative muscles have a higher amount of phospholipids than white glycolytic muscles.

CONVERSION OF MUSCLE TO MEAT

A great number of chemical and biochemical reactions take place in living muscle. Some of these reactions continue, while others are altered due to changes in pH, the presence of inhibitory compounds, the release of ions into the sarcoplasm, and so on during the early postmortem time. In a few hours, these reactions are responsible for the conversion of muscle to meat; this process is basically schematized in Figure 15.2 and consists of the following steps: Once the animal is slaughtered, the blood circulation is stopped, and the importation of nutrients and the removal of metabolites to the muscle cease. This fact has very important

Table 15.5. Example of Fatty Acid Composition (Expressed as Percentage of Total Fatty Acids) of Muscle *Longissimus Dors*i and Adipose Tissue in Pigs Feeded with a Highly Unsaturated Feed. Neutral and Polar Fractions of Muscle Lipids are also Included

Fatty Acid	Total	Muscle Neutral	Polar	Adipose Tissue

Total PUFA	20.84	13.41	50.70	29.17
Ratio MUFA/SFA	1.01	1.15	0.33	0.91
Ratio PUFA/SFA	0.53	0.33	1.37	0.79

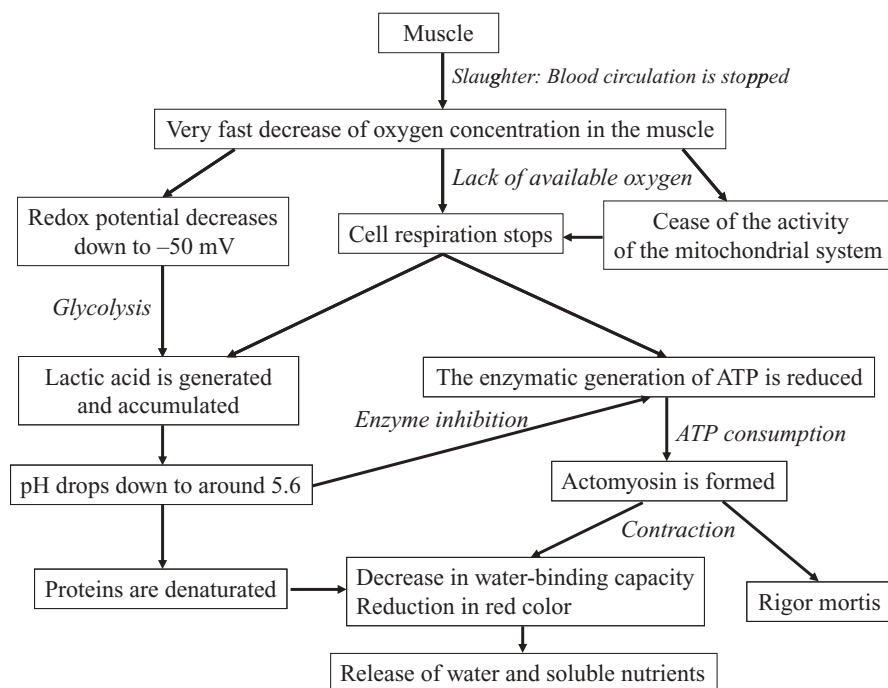
SFA, saturated fatty acids; MUFA, monosaturated fatty acids; PUFA, polysaturated fatty acid.


Figure 15.2. Summary of main changes during conversion of muscle to meat.

and drastic consequences. The first consequence is the reduction of the oxygen concentration within the muscle cell because the oxygen supply has stopped. An immediate consequence is a reduction in mitochondrial activity and cell respiration (Pearson 1987). Under normal aerobic values (see an example of resting muscle in Fig. 15.3), the muscle is able to produce 12 moles of adenosine triphosphate (ATP) per mole of glucose, and thus the ATP content is kept around 5–8 µmol/g of muscle (Greser 1986). ATP constitutes the main source of energy for the contraction and relaxation of the muscle structures as well as other biochem-

Figure 15.3. Comparison of energy generation between resting and stressed muscles.

ical reactions in postmortem muscle. As the redox potential is reduced toward anaerobic values, ATP generation is more costly. So, only 2 moles of ATP are produced per mole of glucose under anaerobic conditions (an example of a stressed muscle is shown in Fig. 15.3). The extent of anaerobic glycolysis depends on the reserves of glycogen in the muscle (Greaser 1986). Glycogen is converted to dextrins, maltose, and finally, glucose through a phosphorolytic pathway; glucose is then converted into lactic acid with the synthesis of 2 moles of ATP (Eskin 1990). In addition, the enzyme creatine kinase may generate some additional ATP from adenosine diphosphate (ADP) and creatine phosphate at very early postmortem times, but only while creatine phosphate remains. The contents of creatine have been reported to vary depending on the type of muscle (Mora et al. 2008). The main steps in glycolysis are schematized in Figure 15.4.

The generation of ATP is strictly necessary in the muscle to supply the required energy for muscle contraction and relaxation and to drive the sodium-potassium pump of the membranes and the calcium pump in the sarcoplasmic reticulum. The initial situation in postmortem muscle is rather similar to that in the stressed muscle, but with an important change: the absence of blood circulation. Thus, there is a lack of nutrient supply and waste removal (see Fig. 15.5). Initially, the ATP content in postmortem muscle does not drop substantially because some ATP may be formed from ceratin phosphate through the action of the enzyme creatine kinase and through anaerobic glycolysis. As mentioned earlier, once creatine phosphate and glycogen are exhausted, ATP drops within a few hours to negligible

Enzymes	Reactions	Other	Comments
Hexokinase	Glucose → glucose-6-P	ATP → ADP	Requires Mg^{2+}
Phosphoglucoisomerase	Glucose-6-P → fructose-6-P		Requires Mg^{2+}
Phosphofructokinase	Fructose-6-P → fructose-1,6-biP	ATP → ADP	Inhibited by excess of ATP Requires Mg^{2+}
Aldolase	Fructose-1,6-biP → dihydroxyacetone-3-P ↓↑ Fructose-1,6-biP → glyceraldehyde-3-P		
Triose phosphate dehydrogenase	Glyceraldehyde-3-P → 1,3diphosphoglycerol	$2NAD^+ → 2NADH$	
Phosphoglycerokinase	1,3-Diphosphoglycerol → 3-phosphoglycerol	2ADP → 2ATP	Requires Mg^{2+}
Phosphoglyceromutase	3-Phosphoglycerol → 2-phosphoglycerol		Requires Mg^{2+}
Enolase	2-Phosphoglycerol → phosphoenolpyruvate	$+ H_2O$	
Pyruvate kinase	Phosphoenolpyruvate → pyruvic acid	2ADP → 2ATP	If O_2 available, produces CO_2 via TCA cycle Requires K^+, Mg^{2+}
Lactate dehydrogenase	Pyruvic acid → lactic acid	$NADH → NAD^+$	Only under anaerobic conditions

Figure 15.5. Scheme of energy generation in postmortem muscle.

values by conversion into ADP, adenosine monophosphate, and other derived compounds such as 5′-inosine monophosphate, 5′-guanosine monophosphate, and inosine (see Fig. 15.6). An example of the typical content of ATP breakdown products in pork at 2 hours and 24 hours postmortem is shown in Table 15.6. The reaction rates depend on the metabolic status of the animal prior to slaughter. For instance, reactions proceed very quickly in pale, soft, exudative (PSE) muscle, where ATP can be almost fully depleted within few minutes. The rate is also affected by the pH and temperature of the meat (Batlle et al. 2000, 2001). For instance, the ATP content in beef *Sternomandibularis* kept at 10–15°C is around 5 μmol/g at 1.5 hours postmortem and decreases to 3.5 μmol/g at 8–9 hours postmortem. However, when that muscle is kept at 38°C, ATP content is below 0.5 μmol/g at 6–7 hours postmortem.

Once the ATP concentration is exhausted, the muscle remains contracted, as no more energy is available for relaxation. The muscle develops a rigid condition known as rigor mortis, in which the crossbridge of myosin and actin remains locked, forming actomyosin (Greaser 1986). The postmortem time necessary for the development of rigor mortis is variable, depending on the animal species, size of carcass, amount of fat cover, and environmental conditions such as the temperature of the chilling
Figure 15.6. Main adenosine triphosphate (ATP) breakdown reactions in early postmortem muscle.

tunnel and the air velocity (see pork pieces after cutting in a slaughterhouse in Fig. 15.7). The rates of enzymatic reactions are strongly affected by temperature. In this sense, the carcass-cooling rate will affect glycolysis rate, pH drop rate, and the time course of rigor onset (Faustman 1994). The animal species and size of carcass have a great influence on the cooling rate

Table 15.6. Example of Nucleotides and Nucleosides Content (Expressed as μmol/g Muscle) in Pork Postmortem Muscle at 2 hours and 24 hours

Compound	2 h Postmortem Time	24 h Postmortem Time
ATP	4.39	—
ADP	1.08	0.25
AMP	0.14	0.20
ITP + GTP	0.18	—
IMP	0.62	6.80
Inosine	0.15	1.30
Hypoxanthine	0.05	0.32

of the carcass. Furthermore, the location in the carcass is also important because surface muscles cool more rapidly than deep muscles (Greaser 2001). So, when carcasses are kept at 15°C, the time required for rigor mortis development may be about 2–4 hours in poultry, 4–18 hours in pork, and 10–24 hours in beef (Toldrá 2006).

Muscle glycolytic enzymes hydrolyze the glucose to lactic acid, which is accumulated in the muscle because muscle waste substances cannot be eliminated due to the absence of blood circulation. This lactic acid accumulation produces a relatively rapid (in a few hours) pH drop to values of about 5.6–5.8. The pH drop rate depends on the glucose concentration, the temperature of the muscle, and the metabolic status of the animal previous to slaughter. Water binding decreases with pH drop because of the change in the protein's charge. Then, some water is released out of the muscle as a drip loss (DL). The amount of released water depends on the extent and rate of pH drop. Soluble compounds such as sarcoplasmic proteins, peptides, free amino acids, nucleotides, nucleosides, B vitamins, and minerals may be partly lost in the drippings, affecting nutritional quality (Toldrá and Flores 2004).

The pH drop during early postmortem has a great influence on the quality of pork and poultry meats. The pH decrease is very fast, below 5.8 after 2 hours postmortem, in muscles from animals with accelerated metabolism. This is the case of the PSE pork meats and red, soft, exudative pork meats. ATP breakdown

Figure 15.7. Pork hams after cutting in a slaughterhouse, ready for submission to a processing plant. (Courtesy of Industrias Cárnicas Vaquero SA, Madrid, Spain.)

also proceeds very quickly in these types of meats, with almost full ATP disappearance in less than 2 hours (Batlle et al. 2001). Red, firm, normal meat experiences a progressive pH drop down to values around 5.8–6.0 at 2 hours postmortem. In this meat, full ATP breakdown may take up to 8 hours. Finally, the dark, firm, dry pork meat (DFD) and dark cutting beef meat are produced when the carbohydrates in the animal are exhausted from before slaughter, and thus almost no lactic acid can be generated during early postmortem due to the lack of a substrate. Very low or almost negligible glycolysis is produced, and the pH remains high in these meats, which constitutes a risk from the microbiological point of view. These meats constitute a risk because they are prone to contamination by foodborne pathogens and must be carefully processed, with extreme attention to good hygienic practices.

Protein oxidation is another relevant change during postmortem aging. Some amino acid residues may be converted into carbonyl derivatives and cause the formation of inter- and intraprotein disulfide links that can reduce the functionality of proteins (Huff-Lonergan 2010).

FACTORS AFFECTING BIOCHEMICAL CHARACTERISTICS

EFFECT OF GENETICS

Genetic Type

The genetic type has an important relevance for quality, not only due to differences among breeds, but also to differences among animals within the same breed. Breeding strategies have been focused toward increased growth rate and lean meat content and decreased backfat thickness. Although grading traits are really improved, poorer meat quality is sometimes obtained. Usually, large ranges are found for genetic correlations between production and meat quality traits, probably due to the reduced number of samples when analyzing the full quality of meat, or to a large number of samples but with few determinations of quality parameters. This variability makes it necessary to combine the results from different research groups to obtain a full scope (Hovenier et al. 1992).

Current pig breeding schemes are usually based on a backcross or on a three- or four-way cross. For instance, a common cross in the European Union is a three-way cross, where the sow is a Landrace × Large White (LR × LW) crossbreed. The terminal sire is chosen depending on the desired profitability per animal, and there is a wide range of possibilities. For instance, the Duroc terminal sire grows faster and shows a better food conversion ratio but accumulates an excess of fat; Belgian Landrace and Pietrain are heavily muscled but have high susceptibility to stress and thus usually present a high percentage of exudative meats; or a combination of Belgian Landrace × Landrace gives good conformation and meat quality (Toldrá 2002).

Differences in tenderness between cattle breeds have also been observed. Brahman cattle is used extensively in the southwest of the United States since it is tolerant to adverse environmental conditions but may give some tenderness issues (Brewer 2010). Even toughness was associated to an increased amount of calpastatin, the endogenous muscle calpain inhibitor (Ibrahim 2008). Studies have been performed for cattle breeding. For instance, after 10 days of aging, the steaks from an Angus breed were more

tender than those from a 1/2Angus–1/2Brahman breed, and more tender than steaks from a 1/4Angus–3/4Brahman breed (Johnson et al. 1990). In other studies, it was found that meat from Hereford cattle was more tender than that from Brahman cattle (Wheeler et al. 1990). Differences in the activity of proteolytic enzymes, especially calpains, that are deeply involved in the degradation of Z-line proteins appear to have a major role in the tenderness differences between breeds.

The enzyme fingerprints, which include the assay of many different enzymes such as endo- and exoproteases as well as lipases and esterases, are useful for predicting the expected proteolysis and lipolysis during further meat processing (Armero et al. 1999a, 1999b). These enzymatic reactions, extensively described in Chapter 14, are very important for the development of sensory characteristics such as tenderness and flavor in meat and meat products.

Genes

Some genes have been found to have a strong correlation to certain positive and negative characteristics of meat. The dominant RN$^-$ allele, also known as the Napole gene, is common in the Hampshire breed of pigs and causes high glycogen content and an extended pH decline. The carcasses are leaner, and the eating quality is better in terms of tenderness and juiciness, but the more rapid pH fall increases DL by about 1%, while the technological yield is reduced by 5–6% (Rosenvold and Andersen 2003, Josell et al. 2003). The processing industry is not interested in pigs with this gene because most pork meat is used for further processing, and the meat from carriers of the RN$^-$ allele gives such a low technological yield (Monin and Sellier 1985).

Pigs containing the halothane gene are stress susceptible, a condition also known as porcine stress syndrome (PSS). These pigs are very excitable in response to transportation and environmental situations, have a very high incidence of PSE, and are susceptible to death due to malignant hyperthermia. These stress-susceptible pigs may be detected through the application of the halothane test, observing their reaction to inhalation anesthesia with halothane (Cassens 2000). These pigs give a higher carcass yield and leaner carcasses, which constitutes a direct benefit for farmers. However, the higher percentage of PSE, with high DL, poor color, and deficient technological properties, makes it unacceptable to the meat processing industry. These negative effects convinced major breeding companies to remove the halothane gene from their lines (Rosenvold and Andersen 2003).

INCIDENCE OF EXUDATIVE MEATS

The detection of exudative meats at early postmortem time is of primary importance for meat processors to avoid further losses during processing. It is evident that PSE pork meat is not appealing to the eye of the consumer because it has a pale color, abundant dripping in the package, and a loose texture (Cassens 2000). Exudative pork meat also generates a loss of the nutrients that are solubilized in the sarcoplasm and lost in the drip and an
Figure 15.8. Typical postmortem pH drop of normal, pale, soft, exudative (PSE) and dark, firm, dry (DFD) pork meats (Toldrá, unpublished).

economic loss due to the lower weight as a consequence of its poor binding properties if the meat is further processed.

PSE meat is the result of protein denaturation at acid pH and relatively high postmortem temperatures. There are several classification methodologies, for example, the measurement of pH or conductivity at 45 minutes postmortem. Other methodologies involve the use of more data and thus give a more accurate profile (Warner et al. 1993, 1997, Toldrá and Flores 2000). So, exudative meats are considered when pH measured at 2 hours postmortem (pH$_{2h}$) is lower than 5.8 and DL is higher than 6%. DL, which is usually expressed as a percent, gives an indication of water loss (difference in weight between 0 and 72 hours): a weighed muscle portion is hung within a sealed plastic bag for 72 hours under refrigeration, then reweighed (Honikel 1997). The color parameter, L, is higher than 50 (pale color) for PSE meats and between 44 and 50 for red exudative (RSE) meats. Meats are considered normal when pH$_{2h}$ is higher than 5.8, L is between 44 and 50, and DL is below 6%. Meats are classified as DFD when L is lower than 44 (dark red color), DL is below 3%, and pH measured at 24 hours postmortem (pH$_{24h}$) remains high. Typical pH drops are shown in Figure 15.8.

There are some measures such as appropriate transport and handling, adequate stunning, and chilling rate of carcasses that can be applied to prevent, or at least reduce, the incidence of negative effects in exudative meats. Even though the problem is well known and there are some available corrective measures, exudative meats still constitute a problem. A survey carried out in the United States in 1992 revealed that 16% of pork carcasses were PSE, 10% DFD, and about 58% of questionable quality, mainly RSE, indicating little progress in the reduction of the problem (Cassens 2000). A similar finding was obtained in a survey carried out in Spain in 1999, where 37% of carcasses were PSE, 12% RSE, and 10% DFD (Toldrá and Flores 2000).

EFFECT OF THE AGE AND SEX

The content in intramuscular fat content increases with the age of the animal. In addition, the meat tends to be more flavorful and colorful, due to an increased concentration of volatiles and myoglobin, respectively (Armero et al. 1999a). Some of the muscle proteolytic and lipolytic enzymes are affected by age. Muscles from heavy pigs (11 months old) are characterized by a greater peptidase to proteinase ratio and a higher lipase, dipeptidylpeptidase IV, and pyroglutamyl aminopeptidase activity. On the other hand, the enzyme activity in light pigs (7–8 months old) shows two groups. The larger one is higher in moisture content and cathepsins B and B+L and low in peptidase activity, while the minor one is intermediate in cathepsin B activity and high in peptidase activity (Toldrá et al. 1996a). In general, there is a correlation between the moisture content and the activity of cathepsins B and B+L (Parolari et al. 1994). So, muscles with higher moisture content show higher levels of cathepsins B and B+L activity. This higher cathepsin activity may produce an excess of proteolysis in processed meat products with long processing times (Toldrá 2002).

A minor effect of sex is observed. Meats from barrows contain more fat than those from gilts. They present higher marbling, and the subcutaneous fat layer is thicker (Armero et al. 1999a). In the case of muscle enzymes, only very minor differences have been found. Sometimes, meats from entire males may give some sexual odor problems due to high contents of androstenone or escatol.

EFFECT OF THE TYPE OF FEED

A great research effort has been exerted since the 1980s for the manipulation of the fatty acid composition of meat, to achieve nutritional recommendations, especially an increase in the ratio between PUFA and saturated fatty acids (SFA) (PUFA:SFA ratio). More recently, nutritionists recommend that PUFA composition should be manipulated toward a lower n-6:n-3 ratio.

Fats with a higher content of PUFA have lower melting points that affect the fat firmness. Softer fats may raise important problems during processing if the integrity of the muscle is disrupted by any mechanical treatment (chopping, mincing, stuffing, etc.). The major troubles are related to oxidation and generation of off-flavors (rancid aromas) and color deterioration (trend toward yellowness in the fat) (Toldrá and Flores 2004).

Pigs and poultry are monogastric animals that incorporate part of the dietary fatty acids practically unchanged into the adipose tissue and cellular membranes, where desaturation and chain elongation processes may occur (Toldrá et al. 1996b, Jakobsen 1999). The extent of incorporation may vary depending on the specific fatty acid and the type of feed. Different types of cereals as well as dietary oils and their effects on the proportions in fatty acid composition have been studied. The use of canola or linseed oils produces a substantial increase in the content of linolenic acid (C 18:3), which is an n-3 fatty acid (Jiménez-Colmenero et al. 2006). In this way, the n-6:n-3 ratio can be reduced from 9 to 5 (Enser et al. 2000). Other dietary oils such as soy, peanut, corn, and sunflower increase the content of linoleic acid (C

18:2), an n-6 fatty acid. Although it increases the total PUFA content, this fatty acid does not contribute to decrease the n-6:n-3 ratio, just the reverse. A similar trend is observed in the case of poultry, where the feeds with a high content of linoleic acid such as grain, corn, plant seeds, or oils also increase the n-6:n-3 ratio (Jakobsen 1999). As in the case of pork, the use of feeds containing fish oils or algae, enriched in n-3 fatty acids such as eicosapentaenoic (C 22:5 n-3) and docosahexanoic (C 22:6 n-3) acids, can enrich the poultry meat in n-3 fatty acids and reduce the n-6:n-3 ratio from around 8.4 to 1.7 (Jakobsen 1999).

The main problem arises from oxidation during heating, because some volatile compounds such as hexanal are typically generated, producing rancid aromas (Larick et al. 1992). The rate and extent of oxidation of muscle foods mainly depends on the level of PUFA, but they are also influenced by early postmortem events such as pH drop, carcass temperature, aging, and other factors. It must be pointed out that the increased linoleic acid content is replacing the oleic acid to a large extent (Monahan et al. 1992). Feeds rich in saturated fats such as tallow yield the highest levels of palmitic, palmitoleic, stearic, and oleic acids in pork loin (Morgan et al. 1992). Linoleic and linolenic acid content may vary as much as 40% between the leanest and the fattest animals (Enser et al. 1988). An example of the effect of feed type on the fatty acid composition of subcutaneous adipose tissue of pigs is shown in Table 15.7. The PUFA content is especially high in phospholipids, located in subcellular membranes such as mitochondria, microsomes, and so on, making them vulnerable to peroxidation because of the proximity of a range of pro-oxidants such as myoglobin, cytochromes, nonheme iron, and trace elements (Buckley et al. 1995). Muscle contains several antioxidant systems, for example, those of superoxide dismutase and glutathione peroxidase, and ceruloplasmin and transferrin, although they are weakened during postmortem storage.

An alternative for effective protection against oxidation consists of the addition of natural antioxidants like vitamin E (alpha-tocopheryl acetate); this has constituted a common practice in the last decade. This compound is added in the feed as an antioxidant and is accumulated by animals in tissues and subcellular structures, including membranes, substantially increasing its effect. The concentration and time of supplementation are important. Usual levels are around 100–200 mg/kg in the feed for several weeks prior to slaughter. The distribution of vitamin E in the organism is variable, being higher in the muscles of the thoracic limb, neck, and thorax and lower in the muscles of the pelvic limb and back (O'Sullivan et al. 1997). Dietary supplementation with this lipid-soluble antioxidant improves the oxidative stability of the meat. Color stability in beef, pork, and poultry is improved by protection of myoglobin against oxidation (Houben et al. 1998, Mercier et al. 1998). The water-holding capacity in pork is improved by protecting the membrane phospholipids against oxidation (Cheah et al. 1995, Dirinck et al. 1996). The reduction in DL by vitamin E is observed even in frozen pork meat, upon thawing. Oxidation of membrane phospholipids causes a loss in membrane integrity and affects its function as a semipermeable barrier. As a consequence, there is an increased passage of sarcoplasmic fluid through the membrane, known as DL.

Table 15.7. Effect of Type of Feed on Total Fatty Acid Composition (Expressed as Percentage of Total Fatty Acids) of Pork muscle Lipids

Fatty Acid\Feed Enriched	Barley + Soybean Meal[a]	Safflower Oil[b]	Tallow Diet[c]	High Oleic Sunflower Oil[d]	Canola Oil[e]
Myristic acid (C 14:0)	–	–	1.37	0.05	1.6
Palmitic acid (C 16:0)	23.86	27.82	24.15	6.35	20.6
Stearic acid (C 18:0)	10.16	12.53	11.73	4.53	9.8
Palmitoleic acid (C 16:1)	3	3.56	3.63	0.45	3.6
Oleic acid (C 18:1)	39.06	37.81	46.22	71.70	45.9
C 20:1	–	0.01	0.29	0.26	
Linoleic acid (C 18:2)	17.15	14.60	8.95	15.96	12.3
C 20:2	–	0.01	0.44	–	0.4
Linolenic acid (C 18:3)	0.91	0.01	0.26	0.71	3.0
C 20:3	0.21	0.01	0.25	–	0.1
Arachidonic acid (C 20:4)	4.26	2.14	2.13	–	0.74
Eicosapentaenoic acid (C 22:5)	0.64	0.01	–	–	–
Hexadecanoic acid (C22:6)	0.75	0.01	–	–	–
Total SFA	34.02	40.35	37.83	10.93	33.6
Total MUFA	42.06	42.38	50.26	72.41	49.5
Total PUFA	23.92	16.79	11.91	16.67	16.6
Ratio MUFA/SFA	1.24	1.05	1.33	6.62	1.47
Ratio PUFA/SFA	0.70	0.42	0.32	1.53	0.49

Sources: [a]Morgan et al. (1992), [b]Larick et al. (1992), [c]Leszczynski et al. (1992), [d]Rhee et al. (1988), [e]Miller et al. (1990).
SFA, saturated fatty acids; MUFA, monosaturated fatty acids; PUFA, polysaturated fatty acid.

The fatty acid profile in ruminants is more saturated than in pigs, and thus the fat is firmer (Wood et al. 2003). The manipulation of fatty acids in beef is more difficult due to the rumen biohydrogenation. More than 90% of the PUFA are hydrogenated, leaving a low margin for action to increase the PUFA:SFA ratio above 0.1. However, meats from ruminants are rich in conjugated linoleic acid (CLA), mainly 9-*cis*,11-*trans*-octadecadienoic acid, which exerts important health-promoting biological activity (Belury 2002).

In general, a good level of nutrition increases the amount of intramuscular fat. On the other hand, food deprivation may result in an induced lipolysis that can be rapidly detected (in just 72 hours) through a higher content of free fatty acids and monoacylglycerols, especially in glycolytic muscles (Fernandez et al. 1995). Fasting within 12–15 hours preslaughter is usual to reduce the risk of microbial cross-contamination during slaughter.

CARCASS CLASSIFICATION

CURRENT GRADING SYSTEMS

Meat grading constitutes a valuable tool for the classification of a large number of carcasses into classes and grades with similar characteristics such as quality and yield. The final purpose is to evaluate specific characteristics to determine carcass retail value. In addition, the weight and category of the carcass are useful for establishing the final price to be paid to the farmer. Carcasses are usually evaluated for conformation, carcass length, and back-fat thickness. The carcass yields vary depending on the degree of fatness and the degree of muscling. The grade

is determined based on both degrees. The grading system is, thus, giving information on quality traits of the carcass that help producers, processors, retailers, and consumers.

Official grading systems are based on conformation, quality, and yield. Yield grades indicate the quantity of edible meat in a carcass. In the United States, beef carcasses receive a grade for quality (prime, choice, good, standard, commercial, utility, and cutter) and a grade for predicted yield of edible meat (1–5). There are four grades for pork carcasses (US No. 1 to US No. 4) based on back-fat thickness and expected lean yield. The lean yield is predicted by a combination of back-fat thickness measured at the last rib and the subjective estimation of the muscling degree. In the case of poultry, there are three grades (A–C) based on the bilateral symmetry of the sternum, the lateral convexity and distal extension of the pectoral muscles, and fat cover on the pectoral muscles (Swatland 1994).

In Europe, beef, pork, and lamb carcasses are classified according to the EUROP scheme (Council regulation 1208/81, Commission directives 2930/81, 2137/92, and 461/93). These European Union Directives are compulsory for all the member states. Carcass classification is based on the conformation according to profiles, muscle development, and fat level. Each carcass is classified by visual inspection, based on photos corresponding to each grade (see Fig. 15.9). The six conformation classification ratings are S (superior), E (excellent), U (very good), R (good), O (fair), and P (poor). S represents the highest quality level and must not present any defect in the main pieces. The five classification ratings for fat level are 1 (low), 2 (slight), 3 (average), 4 (high), and 5 (very high). The grading system for each carcass consists in a letter for conformation, which is given

Figure 15.9. Classification of pork carcasses in the slaughterhouse. (Courtesy of Industrias Cárnicas Vaquero SA, Madrid, Spain.)

Figure 15.10. Example of application of physical-based methods for the online evaluation of meat yield and quality. At the slaughterhouse, the hand-held devices are applied to the carcass between the last three and four ribs (place marked with an *arrow*). The signal is then received in the unit and computer-processed. The carcass quality is estimated and, depending on the technique, is also classified by yield. (Courtesy of Industrias Cárnicas Vaquero SA, Madrid, Spain.)

first, and a number for the fat level. In some countries, additional grading systems may be added. For instance, in France, the color is measured and rated 1 to 4 from white to red color.

New Grading Systems

New grading systems are being developed that take advantage of the rapid developments in video image analysis and other new physical techniques as well as those in biochemical assay tests. New methodologies based on physical methods for the online evaluation of meat yield and meat quality, applied as schematized in Figure 15.10, include near infrared reflectance (NIR), video image analysis, ultrasound, texture analysis, nuclear magnetic resonance, and magnetic resonance spectroscopy techniques.

Physical Techniques

NIR is applied for the rapid and nondestructive analysis of meat composition in fat, protein, and water (Byrne et al. 1998, Rodbotten et al. 2000). This technique has also been applied to aged meat, giving a good correlation with texture, and thus constituting a good predictor for meat tenderness. In addition, NIR spectroscopy allows for a minimal or nonnecessary sample preparation (Niemöller and Behmer 2008). Video image analysis is very useful for the measurement of carcass shape, marbling, and meat color. Conductivity has been in use for several years to predict meat composition and quality.

Ultrasounds are based on the measurement of different parameters such as velocity, attenuation, and backscattering intensity and may constitute a valuable tool for the measurement of meat composition (Got et al. 1999, Abouelkaram et al. 2000). Texture

analysis, as the image processing of the organization of gray pixels of digitized images, can be used for the classification of photographic images of meat slices (Basset et al. 2000). This technique appears to give good correlation with fat and collagen, which are especially visible under ultraviolet light, and would allow classification according to three factors, muscle type, age, and breed (Basset et al. 1999).

Nuclear magnetic resonance has good potential as a noninvasive technique for better characterization and understanding of meat features. Thus, magnetic resonance imaging can give a spatial resolution that characterizes body composition. This technique is well correlated to important meat properties such as pH, cooking yield, and water-holding capacity (Laurent et al. 2000). Magnetic resonance spectroscopy may be useful to determine the fatty acid composition of animal fat. This technique may have further applications; for example, in the possible use of ^{23}Na imaging to follow brine diffusion in cured meat products (Renou et al. 1994).

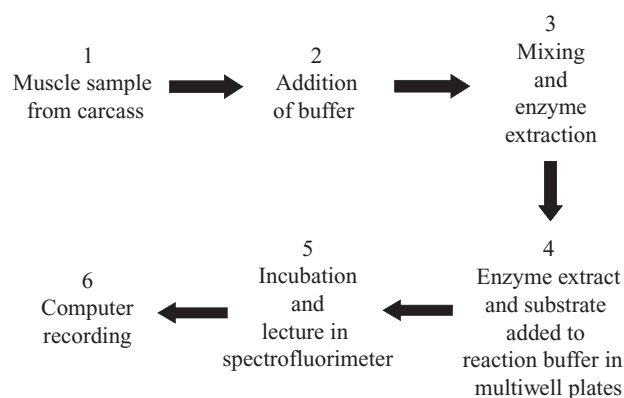
The use of bioimpedance spectroscopy has shown good performance for the assessment of meat quality, especially to distinguish among PSE, DFD, and normal pork meats (Castro-Giráldez et al. 2009, 2010a). The amount of ATP is characteristic for each type of pork meat quality and the ion activity of ATP may be correlated with the ionic dispersion in the dielectric spectra (Castro-Giráldez et al. 2010b).


Figure 15.11. Example of application of biochemical-based methods for evaluation of meat quality. A sample of the carcass (1) is mixed with buffer (2) for enzyme extraction and homogenization (3). Enzyme extracts are placed in the wells of a multiwell plate and synthetic substrates, previously dissolved in reaction buffer, are added (4). The released fluorescence, which is proportional to the enzyme activity, is read by a multiwell plate spectrofluorometer (5) and computer-recorded (6).

Biochemical Assay Techniques

Biochemical assay methodologies are based on biochemical compounds that can be used as markers of meat quality. The mode of operation is essentially schematized in Figure 15.11. Some of the most promising techniques include assay of proteolytic muscle enzymes and use of peptides as biochemical markers.

The assay of certain proteolytic muscle enzymes such as calpain I, alanyl aminopeptidase, or dipeptidylpeptidase IV at just 2 hours postmortem, has shown good ability to predict the water-holding capacity of the meat (Toldrá and Flores 2000). Modified assay procedures, based on the use of synthetic fluorescent substrates, have been developed to allow relatively fast and simple measurements of enzyme activity with enough sensitivity.

Some peptides have been proposed as biochemical markers for meat tenderness, which is particularly important in beef. These are peptides with molecular masses ranging from 1282 to 5712 kDa, generated from sarcoplasmic and myofibrillar proteins (Stoeva et al. 2000). The isolation and identification of these peptides are tedious and time consuming, but once the full sequence is known, Enzyme-linked immunosorbent assay (ELISA) test kits can be developed, and this would allow rapid assay and online detection at the slaughterhouse.

BIOACTIVE COMPOUNDS

It is well known that meat contains a large amount of proteins with high biological value. However, in recent years, the bioactivities of certain compounds that are present in meat, even though in minor amounts, have received increased attention because they may have an important nutritional role.

CLA is a group of isomers of octadecadienoic acid that is abundant in the fat of ruminants like cattle and sheep. The content may change depending on the breed, feed, and age. CLA has been reported to reduce the risk for certain types of cancer like the colorectal cancer as well as having other activities like antiartherioesclerotic, antioxidative, and also playing certain role in controlling obesity (Arihara and Motoko 2010).

Some of these substances are small peptides, which are present in meat. Dipeptides carnosine and anserine are present in meat although their content varies depending on the animal species and the type of muscle metabolism (Aristoy et al. 2004, Aristoy and Toldrá 2004, Mora et al. 2008). Both peptides have shown good resistance to proteases and a good antioxidant activity. Other bioactive peptides are derived from meat proteins after digestion. These peptides exert an antihypertensive effect through the inhibitory action on the angiotensin I converting enzyme. So, several bioactive peptides have been identified and sequenced after simulated in vitro gastrointestinal digestion of pork meat proteins (Escudero et al. 2010a, 2010b).

In summary, there are many biochemical and chemical reactions of interest in raw meats that contribute to important changes in meat and affect its quality. Most of these changes, as described in this chapter, have an important role in defining the aptitude of the meat as raw material for further processing.

Biochemistry of Processing Meat and Poultry

Fidel Toldrá

Abstract: The biochemical changes happening during meat conditioning (aging) were abundantly reported during the 1970s and 1980s. It has been in recent decades that more information has been available for the biochemical changes in other products such as cooked, dry-fermented, and dry-cured meats. The processing and quality of these meat products have been improved based on a better knowledge of the biochemical mechanisms involved in the genera-
tion of color, flavor, and texture. The endogenous enzyme systems that play important roles in these processes mainly through proteolysis and lipolysis reactions are described in this chapter. Other biochemical reactions like oxidation, glycolysis, and nucleotides breakdown are also described.

BACKGROUND INFORMATION

There are a wide variety of meat products that are attractive to consumers because of their characteristic color, flavor, and texture. This perception varies depending on local traditions and heritage. Most of these products have been produced for many years or even centuries based on traditional practices. For instance, cured meat products reached America with settlers. Pork was cured in New England for consumption in the summer. Curers expanded these products by trying different recipes based on the use of additives such salt, sugar, pepper, spices, and so forth, and smoking (Toldrá 2002).

Although scientific literature on biochemical changes during meat conditioning (aging) and in some meat products were abundantly reported during the 1970s and 1980s, little information was available on the origin of the biochemical changes in other products such as cooked, dry-fermented, and dry-cured meats. The need to improve the processing and quality of these meat products prompted research in the last decades on endogenous enzyme systems that play important roles in these processes, which has been later demonstrated (Toldrá 2007). It is important to remember that the potential role of a certain enzyme in a specific observed or reported biochemical change can only be established if all the following requirements are met (Toldrá 1992): (1) the enzyme is present in the skeletal muscle or adipose tissue, (2) the enzyme is able to degrade in vitro the natural substance (i.e., a protein in the case of a protease, a triacylglycerol in the case of a lipase, etc.), (3) the enzyme and substrate

are located close enough in the real meat product for an effective interaction, and (4) the enzyme exhibits enough stability during processing for the changes to be developed.

DESCRIPTION OF THE MUSCLE ENZYMES

There are a wide variety of enzymes in the muscle. Most of them have an important role in the in vivo muscle functions, but they also serve an important role in biochemical changes such as the proteolysis and lipolysis that occur in postmortem meat, and during further processing of meat. Some enzymes are located in the lysosomes, while others are free in the cytosol or linked to membranes. The muscle enzymes with most important roles during meat processing are grouped by families and are described in the succeeding sections.

Muscle Proteases

Proteases are characterized by their ability to degrade proteins, and they receive different names depending on respective mode of action (see Fig. 16.1). They are endoproteases or proteinases, when they are able to hydrolyze internal peptide bonds, but they are exopeptidases, when they hydrolyze external peptide bonds, either at the amino termini or the carboxy termini.

Neutral Proteinases: Calpains

Calpains are cysteine endopeptidases consisting of heterodimers of 110 kDa, composed of an 80 kDa catalytic subunit and a 30 kDa subunit of unknown function. They are located in the cytosol, around the Z-line area. Calpains have received different names in the scientific literature, such as calcium-activated neutral proteinase, calcium-dependent protease, and calcium-

Figure 16.1. Mode of action of the different types of muscle proteases.

activated factor. Calpain I is also called μ-calpain because it needs micromolar amounts (50–70 μM) of Ca^{2+} for activation. Similarly, calpain II is called m-calpain because it requires millimolar amounts (1–5 mM) of Ca^{2+}. Both calpains show maximal activity around pH 7.5. Calpain activity decreases very quickly when pH decreases to 6.0, or even reaches ineffective activity at pH 5.5 (Etherington 1984). Calpains have shown good ability to degrade important myofibrillar proteins, such as titin, nebulin, troponins T and I, tropomyosin, C-protein, filamin, desmin, and vinculin, which are responsible for the fiber structure. On the other hand, they are not active against myosin, actin, α-actinin and troponin C (Goll et al. 1983, Koohmaraie 1994).

The stability of calpain I in postmortem muscle is very poor because it is readily autolyzed, especially at high temperatures, in the presence of the released Ca^{2+} (Koohmaraie 1994). Calpain II appears as more stable, just 2–3 weeks before losing its activity (Koohmaraie et al. 1987). In view of this rather poor stability, the importance of calpains should be restricted to short-term processes. A minor contribution, just at the beginning, has been observed in long processes such as dry curing of hams (Rosell and Toldrá 1996) or in fermented meats where the acid pH values makes calpain activity rather unlikely (Toldrá et al. 2001).

Calpastatin is a polypeptide (between 50 and 172 kDa) acting as an endogenous reversible and competitive inhibitor of calpain in the living muscle. In postmortem muscle, calpastatin regulates the activity of calpains, through a calcium-dependent interaction, although only for a few days, because it is destroyed by autolysis (Koohmaraie et al. 1987). The levels of calpastatin vary with animal species, and pork muscle has the lowest level (Valin and Ouali 1992).

Lysosomal Proteinases: Cathepsins

There are several acid proteinases in the lysosomes that degrade proteins in a nonselective way. The most important are cathepsins B, H, and L, which are cysteine proteinases, and cathepsin D, which is an aspartate proteinase. The optimal pH for activity is slightly acid (pH around 6.0) for cathepsins B and L, acid (pH around 4.5) for cathepsin D, and neutral (pH 6.8) for cathepsin H (Toldrá et al. 1992). Cathepsins require a reducing environment such as that found in postmortem muscle to express their optimal activity (Etherington 1987). All of them are of small size, within the range 20–40 kDa, and are thus able to penetrate into the myofibrillar structure. Cathepsins have shown a good ability to degrade different myofibrillar proteins. Cathepsins D and L are very active against myosin heavy chain, titin, M and C proteins, tropomyosin, and troponins T and I (Matsukura et al. 1981, Zeece and Katoh 1989). Cathepsin L is extremely active in degrading both titin and nebulin. Cathepsin B is able to degrade myosin heavy chain and actin (Schwartz and Bird 1977). Cathepsin H exhibits both endo- and aminopeptidase activity, and this is the reason for its classification as an aminoendopeptidase (Okitani et al. 1981). In the muscle, there are endogenous inhibitors against cysteine peptidases. These inhibitory compounds, known as cystatins, are able to inhibit cathepsins B, H, and L. Cystatin C and chicken cystatin are the most well-known cystatins.
Proteasome Complex

The proteasome is a multicatalytic complex with different functions in living muscle, even though its role in postmortem muscle is still not well understood. The 20S proteasome has a large molecular mass, 700 kDa, and a cylinder structure with several subunits. Its activity is optimal at pH above 7.0, but it rapidly decreases when pH decreases, especially below 5.5. It exhibits three major activities: (1) chymotrypsin-like activity, (2) trypsin-like activity, and (3) peptidyl-glutamyl hydrolyzing activity (Coux et al. 1996). This multiple activity behavior is the reason why there was originally some confusion among laboratories over its identification. The 20S proteasome concentration is higher in oxidative muscles than in glycolytic ones (Dahlmann et al. 2001). This enzyme has shown degradation of some myofibrillar proteins such as troponin C and myosin light chain and could be involved in postmortem changes in slow twitch oxidative muscles or in high-pH meat, where an enlargement of the Z-line with more or less density loss is observed (Sentandreu et al. 2002).

A new family of peptidases, named as caspases or apoptosis-generating peptidases, are cysteine peptidases that have been recently proposed to be involved in cell death and thus immediate postmortem changes in proteins having some impact on the phases of rigor and meat aging. Three main pathways of cellular death development have been proposed (Herrera-Méndez et al. 2006). These peptidases are active at neutral pH, and one of the limitations to its activity in postmortem meat is the acid pH in the postmortem muscle.

Exoproteases: Peptidases

There are several peptidases in the muscle with the ability to release small peptides of importance for taste. Tripeptidylpeptidases (TPPs) are enzymes capable of hydrolyzing different tripeptides from the amino termini of peptides, while dipeptidylpeptidases (DPPs) are able to hydrolyze different dipeptide sequences. There are two TPPs and four DPPs, and their molecular masses are relatively high, between 100 and 200 kDa, or even as high as 1000 kDa for TPP II, and have different substrate specificities. TPP I is located in the lysosomes, has an optimal acid pH (4.0), and is able to hydrolyze tripeptides Gly-Pro-X, where X is an amino acid, preferentially of hydrophobic nature. TPP II has optimal neutral pH (6.5–7.5) and wide substrate specificity, except when Pro is present on one of both sides of the hydrolyzed bond. DPPs I and II are located in the lysosomes and have optimal acid pH (5.5). DPP I has a special preference for hydrolyzing the dipeptides Ala-Arg and Gly-Arg, while DPP II prefers a terminal Gly-Pro sequence. DPP III is located in the cytosol and has special preference for terminal Arg-Arg and Ala-Arg sequences. DPP IV is linked to the plasma membrane and prefers a terminal Gly-Pro sequence. Both DPP III and IV have an optimal pH around 7.5–8.0. All these peptidases have been purified and fully characterized in porcine skeletal muscle (Toldrá 2002).

Exoproteases: Aminopeptidases and Carboxypeptidases

There are five aminopeptidases, known as leucyl, arginyl, alanyl, pyroglutamyl, and methionyl aminopeptidases, based on their respective preference or requirement for a specific N-terminal amino acid. They are able, however, to hydrolyze other amino acids, although at a lower rate (Toldrá 1998). Aminopeptidases are metalloproteases with a very high molecular mass and complex structures. All of them are active at neutral or basic pH. Alanyl aminopeptidase, also known as the major aminopeptidase because it exhibits very high activity, is characterized by its preferential hydrolysis of alanine, but it is also able to act against a wide spectrum of amino acids such as aromatic, aliphatic, and basic aminoacyl bonds. Methionyl aminopeptidase has preference for methionine, alanine, lysine, and leucine, but also has a wide spectrum of activity. This enzyme is activated by calcium ions. Arginyl aminopeptidase, also known as aminopeptidase B, hydrolyzes basic amino acids such as arginine and lysine (Toldrá and Flores 1998).

Carboxypeptidases are located in the lysosomes and have optimal acid pH. They are able to release free amino acids from the carboxy termini of peptides and proteins. Carboxypeptidase A has preference for hydrophobic amino acids, whereas carboxypeptidase B has a wide spectrum of activity (McDonald and Barrett 1986).

LIPOLYTIC ENZYMES

Lipolytic enzymes are characterized by their ability to degrade lipids, and they receive different names depending on their mode of action (see Fig. 16.2). They are known as lipases when they are able to release long-chain fatty acids from triacylglycerols, while they are know as esterases when they act on short-chain fatty acids. Lipases and esterases are located either in the skeletal muscle or in the adipose tissue. Phospholipases, mainly found in the skeletal muscle, hydrolyze fatty acids at positions 1 or 2 in phospholipids.

Figure 16.2. Mode of action of muscle lipases and phospholipases.

Muscle Lipases

Lysosomal acid lipase and acid phospholipase are located in the lysosomes. Both have an optimal acid pH (4.5–5.5) and are responsible for the generation of long-chain free fatty acids. Lysosomal acid lipase has preference for the hydrolysis of tri-acylglycerols at positions 1 or 3 (Fowler and Brown 1984). This enzyme also hydrolyzes di- and monoacylglycerols but at a lower rate (Imanaka et al. 1985, Negre et al. 1985). Acid phospholipase hydrolyzes phospholipids at position 1 at the water-lipid interface.

Phospholipase A and lysophospholipase have optimal pH in the basic region and regulate the hydrolysis of phospholipids, at positions 1 and 2, respectively. The activities of these enzymes are higher in oxidative muscles than in glycolytic muscles, and this fact would explain the high content of free fatty acids in oxidative muscles. The increase in activity is about 10- to 25-fold for phospholipase A and 4- to 5-fold for lysophospholipase (Alasnier and Gandemer 2000).

Acid and neutral esterases are located in the lysosomes and cytosol, respectively, and are quite stable (Motilva et al. 1992). Esterases are able to hydrolyze short-chain fatty acids from tri-, di-, and monoacylglycerols, but they exert poor action due to the lack of adequate substrate.

Adipose Tissue Lipases

Hormone-sensitive lipase is the most important enzyme present in adipose tissue. This enzyme is responsible for the hydrolysis of stored adipocyte lipids. It has a high specificity and prefer-ence for the hydrolysis of long-chain tri- and diacylglycerols (Belfrage et al. 1984). This enzyme has positional specificity since it hydrolyzes fatty acids at positions 1 or 3 in triacylglyc-erols four times faster than it hydrolyzes fatty acids in position 2 (Belfrage et al. 1984). The hormone-sensitive lipase has a molecular mass of 84 kDa and neutral optimal pH, around 7.0. The monoacylglycerol lipase is mainly present in the adipocytes, and very little is present in stromal and vascular cells. It has a molecular mass of 32.9 kDa and hydrolyzes medium- and long-chain monoacylglycerols resulting from previous hydrolysis by the hormone-sensitive lipase (Tornquist et al. 1978). Lipopro-tein lipase is located in the capillary endothelium and is able to hydrolyze the acylglycerol components at the luminal surface of the endothelium (Smith and Pownall 1984), with preference for fatty acids at position 1 over those at position 3 (Fielding and Fielding 1980). Lipoprotein lipase is an acylglycerol lipase responsible for the degradation of lipoprotein triacylglycerol. Its molecular mass is around 60 kDa and it has an optimal basic pH. Unsaturated monoacylglycerols are more quickly hydrolyzed than saturated compounds (Miller et al. 1981).

The lipolysis phenomenon in adipose tissue is not so complex as in muscle. The hormone-sensitive lipase hydrolyzes tri- and diacylglycerols, as a rate-limiting step (Xiao et al. 2010). The resulting monoacylglycerols from this reaction or from lipopro-tein lipase (Belfrage et al. 1984) are then further hydrolyzed by the monoacylglycerol lipase. The end products are glycerol and free fatty acids.

Acid and neutral esterases are also present in adipose tissue (Motilva et al. 1992). During mobilization of depot lipids, es-terases can participate by mobilizing stored cholesteryl esters. Esterases can also degrade lipoprotein cholesteryl esters taken up from the plasma (Belfrage et al. 1984).

MUSCLE OXIDATIVE AND ANTIOXIDATIVE ENZYMES

Oxidative Enzymes

Lipoxygenase contains iron and catalyzes the incorporation of molecular oxygen into polyunsaturated fatty acids, especially arachidonic acid, and esters containing a Z,Z-1,4-pentadien (Marczy et al. 1995). They receive different names, 5-, 12-, or 15-lipoxygenase, depending on the position where oxygen is introduced. The final product is a conjugated hydroperoxide. They usually require millimolar concentrations of Ca^{+2}, and their activity is stimulated by ATP (Yamamoto 1992). Lipoxy-genase has been found to be stable during frozen storage and is responsible for rancidity development in chicken, especially in the muscle *Gastrocnemius* (Grossman et al. 1988).

Antioxidative Enzymes

Antioxidative enzymes and their regulation in the muscle consti-tute a defense system against oxidative susceptibility (i.e., an in-creased concentration of polyunsaturated fatty acids) and physi-cal stress (Young et al. 2003). Glutathione peroxidase contains a covalently bound selenium atom that is essential for its activity. This enzyme catalyzes the dismutation of alkyl hydroperoxides by reducing agents like phenols. Its activity has been reported to be lower in oxidative muscles than in glycolytic muscles (Daun et al. 2001). Superoxide dismutase is a copper metalloenzyme, and catalase an iron metalloenzyme. Both enzymes catalyze the dismutation of hydrogen peroxide to less harmful hydroxides. These enzymes influence the shelf life of the meat and pro-tect against the pro-oxidative effects of chloride during further processing.

PROTEOLYSIS

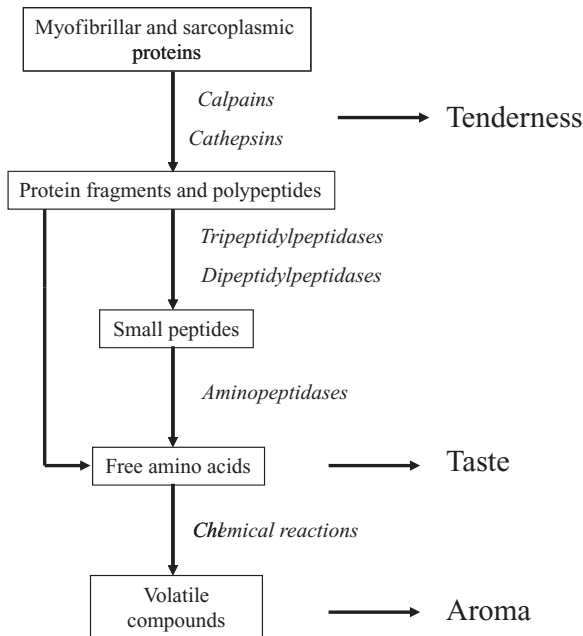
Proteolysis constitutes an important group of reactions during the processing of meat and meat products. In fact, proteolysis has a high impact on texture, and thus meat tenderness, because it contributes to the breakdown of the myofibrillar proteins respon-sible for muscle network, but proteolysis also generates peptides and free amino acids that have a direct influence on taste and also act as substrates for further reactions contributing to aroma (Toldrá 1998, 2002). In general, proteolysis has several consec-utive stages (see Fig. 16.3) as follows: (1) action of calpains and cathepsins on major myofibrillar proteins, generating protein fragments and intermediate size polypeptides; (2) these gener-ated fragments and polypeptides are further hydrolzyed to small peptides by DPPs and TPPs; and (3) dipeptidases, aminopepti-dases, and carboxypeptidases are the last proteolytic enzymes that act on previous polypeptides and peptides to generate free amino acids. The progress of proteolysis varies depending on


Figure 16.3. General scheme of proteolysis during the processing of meat and meat products.

Figure 16.4. Evolution of muscle cathepsins during the aging of beef (Toldrá, unpublished data).

the processing conditions, the type of muscle, and the amount of endogenous proteolytic enzymes, as described later.

PROTEOLYSIS IN AGED MEAT AND COOKED MEAT PRODUCTS

During meat aging, there is proteolysis of important myofibrillar proteins such as troponin T by calpains, with the associated release of a characteristic 30 kDa fragment, which is associated with meat tenderness, nebulin, desmin, titin, troponin I, myosin heavy chain, and proteins at the Z-line level (Yates et al. 1983). A 95 kDa fragment is also characteristically generated (Koohmaraie 1994). Examples of cathepsin and aminopeptidase activity during beef aging are shown in Figures 16.4 and 16.5, respectively.

The fastest aging rate is observed in chicken, followed by pork, lamb, and beef. For instance, it has been reported that chicken myofibrils are easily damaged by cathepsin L, whereas beef myofibrils are much more resistant (Mikami et al. 1987). The reasons for this difference are the differences between species in enzymatic activity, inhibitor content, and susceptibility to proteolysis of the myofibrillar structure. These factors are also strongly linked to the type of muscle metabolism, which has a strong influence on the aging rate (Toldrá 2006a). In fact, proteolysis is faster in fast-twitch white fibers (which contract rapidly) than in slow-twitch red fibers (which contract slowly), that is, aging rate increases with increasing speed of contraction but decreases with the level of heme iron (Ouali 1991). Even though the effect of muscle type is estimated to be tenfold lower

than the effect of temperature, it is threefold higher than animal effects (Dransfield 1980–1981). There are also some physical and chemical conditions in postmortem muscle, listed in Tables 16.1 and 16.2, respectively, that can affect enzyme activity. Of these conditions, the most significant are pH, which decreases once the animal is slaughtered, and osmolality, which increases from 300 to around 550 mOsm within 2 days, due to the release of ions to the cytosol. The osmolality has been observed to be higher in fast-twitch muscle, which also experiences a faster aging rate (Valin and Ouali 1992). Age of the animal also decreases the aging rate, because collagen content as well as the cross-links that make the muscle more heat stable and mechanically resistant, increase with age.

PROTEOLYSIS IN FERMENTED MEATS

The progressive pH decrease by lactic acid (generated during the fermentation by lactic acid bacteria), the added salt (2–3%),
Figure 16.5. Evolution of muscle aminopeptidases during the aging of beef (Adapted from Goransson et al. 2002).

Table 16.1. Physical Factors Affecting Proteolytic Activity During Meat and Meat Products Processing

Factor	Typical Trend	Effect on Proteases
pH	Near neutral pH in dry-cured ham and cooked meat products.	Favors the activity of calpain, cathepsins B and L, DPP III and IV, TPP II and aminopeptidases.
	Slightly acid in aged meat	Favors the activity of cathepsins B, H and L
	Acid pH in dry-fermented sausages	Favors the activity of cathepsin D, DPP I, DPP II, and TPP I
Time	Short in aged meat, cooked meat products, and fermented products	Short action for enough enzyme action except for calpains that contribute to tenderness
	Medium in dry-fermented sausages	Time allows significant biochemical changes
	Long in dry-cured ham	Very long time for important biochemical changes
Temperature	High increase in cooking and smoking	Enzymes are strongly activated by cooking temperatures although stability decreases rapidly and time of cooking is short
	Mild temperatures in fermentation and dry-curing	Enzymes have time enough for its activity even though the use of mild temperatures
Water activity	Slightly reduced in cooked meats	Enzymes have good conditions for activity
	Substantially reduced in dry-meats.	Restricted enzyme activity as aw drops
Redox potential	Anaerobic values in postmortem meat.	Most of the muscle enzymes need reducing conditions for activity
Osmolality	High in fast-twitch muscle. It may increase from 300 to 550 mOsm within 2 d	Enhances proteases activity and these muscles are aged at faster rate

and the heating/drying conditions during the fermentation and ripening/drying affect protein solubility (Toldrá and Reig 2007). The reduction may reach 50–60% in the case of myofibrillar proteins and 20–47% for sarcoplasmic proteins (Klement et al. 1974). There is a variable degree of contribution to proteolysis by both endogenous and proteases and those of microbial origin. This contribution mainly depends on the raw materials, the type of product, and the processing conditions. The contribution of microbial proteases to proteolysis also depends on the type of strains. For instance, strains *Staphylococcus carnosus* and *Staphylococcus simulans* were reported to hydrolyze sarcoplasmic but not myofibrillar proteins; however, no protease activity was detected in another staphylococci but instead, some low aminopeptidase and high esterase activity was found (Casaburi et al. 2006).

The pH drop during the fermentation stage is very important. So, when pH drops below 5.0, the proteolytic activity of endogenous cathepsin D becomes very intense (Toldrá et al. 2001). Several myofibrillar proteins, such as myosin and actin, are degraded, and some fragments of 135, 38, 29 kDa, and 13 kDa are formed. The major role of cathepsin D has been confirmed in model systems using antibiotics and specific protease inhibitors in order to inhibit bacterial proteinases or other endogenous muscle proteinases (Molly et al. 1997). A minor role is played by other muscle cathepsins (B, H, and L) and bacterial proteinases. Peptides and small protein fragments are produced during fermentation, heating (smoking), and ripening. The generation of free amino acids, as final products of proteolysis, depends on the pH reached in the product (as aminopeptidases are affected by low pH values), concentration of salt (these enzymes are

Table 16.2. Chemical Factors Affecting Proteolytic Activity During Meat and Meat Products Processing

Factor	Typical Trend	Effect on Proteases
NaCl	Low in aged meat	No effect on enzyme activity
	Medium concentration in cooked meat products	Partial inhibition of most proteases except calpain and aminopeptidase B that are chloride-activated at low NaCl concentration.
	High concentration in dry-cured hams	Strong inhibition of almost all proteases
Nitrate and nitrite	Concentration around 125 ppm in cured meat products	Slight inhibitory effect on the enzyme activity, except cathepsin B that is activated
Ascorbic acid	Concentration around 500 ppm in cured meat products	Slight inhibition of *m*-calpain, cathepsin H, leucyl aminopeptidase, and aminopeptidase B
Glucose	Poor concentration in aged meat and dry-cured ham	No effect
	High concentration (up to 2 gL^{-1}) in fermented meats	Slight activation of leucyl aminopeptidase and cathepsins B, H, and D

inhibited or activated by salt), and processing conditions (time, temperature, and water activity (a_w) that affect the enzyme activity) (Toldrá 1998). All these factors affect the contribution of the different aminopeptidases, as described in Tables 16.1 and 16.2; thus, the pH reached at the fermentation stage (pH < 5.0) is decisive because it reduces substantially both muscle and microbial aminopeptidase activity (Sanz et al. 2002). So, the processing environmental conditions at the beginning of drying are very important for the accumulation of free amino acids in the final products (Roseiro et al. 2010).

Finally, it must be taken into account that some microorganisms, grown during fermentation, might have decarboxylase (an enzyme able to generate amines from amino acids) activity.

PROTEOLYSIS IN DRY-CURED HAM

The analysis of muscle sarcoplasmic proteins and myofibrillar proteins by sodium dodecyl sulfate–polyacrylamide gel electrophoresis reveals an intense proteolysis during the process. This proteolysis appears to be more intense in myofibrillar than in sarcoplasmic proteins (Toldrá and Aristoy 2010). The patterns for myosin heavy chain, myosin light chains 1 and 2, and troponins C and I show a progressive disappearance during the processing (Toldrá et al. 1993). Several fragments of 150, 95, and 16 kDa and in the ranges of 50–100 kDa and 20–45 kDa are formed (Toldrá 2002). The analysis of ultrastructural changes by both scanning and transmission electron microscopy shows weakening of the Z-line as well as important damage to the fibers, especially at the end of salting (Monin et al. 1997). An excess of proteolysis may create unpleasant textures because of intense structural damage. The result is a poor firmness that is poorly rated by sensory panelists and consumers. This excess of proteolysis is frequently due to the breed type and/or age, which have a marked influence on some enzymes, or just a higher level of cathepsin B activity (Toldrá 2004a). A high residual cathepsin B activity and/or low salt content, a strong inhibitor of cathepsin activity, are correlated with the increased softness. The action of calpains is restricted to the initial days of processing due to their poor stability. Cathepsin D would contribute during the initial 6 months, and cathepsins B, L, and H, which are very stable and have an optimal pH closer to that in ham, would act during the full process (Toldrá 1992). An example of the evolution of these enzymes is shown in Figure 16.6.

Numerous peptides are generated during processing: mainly in the range 2700–4500 Da during postsalting and early ripening, and below 2700 Da during ripening and drying (Aristoy and Toldrá 1995). Some of these peptides have been generated from specific myofibrillar and sarcoplasmic proteins degradation. Proteomic tools have been used for the identification of long-chain peptides resulting from proteolysis of actin (Sentandreu et al. 2007), titin, and light-chain myosin I (Mora et al. 2009a) and creatine kinase (Mora et al. 2009b). These peptides are object of further research for its potential bioactivity and contribution to the nutritional properties of dry-cured ham (Jiménez-Colmenero et al. 2010). Some of the smaller tri- and dipeptides recently have been sequenced. DPP I and TPP I appear to be the major enzymes involved in the release of di- and tripeptides, respectively, due
Figure 16.6. Evolution of cathepsins during the processing of dry-cured ham (Toldrá, unpublished data).

to their good activity, stability, and an optimal pH near to that in ham. The other peptidases would play a minor role (Sentandreu and Toldrá 2002). The generation of free amino acids during the processing of dry-cured ham is very high (Toldrá 2004b). Alanine, leucine, valine, arginine, lysine, and glutamic and aspartic acids are some of the amino acids generated in higher amounts. An example of generation is shown in Figure 16.7. The final concentrations depend on the length of the process and the type of ham (Toldrá et al. 2000). On the basis of the specific enzyme characteristics and the process conditions, alanyl and methionyl aminopeptidases appear to be the most important enzymes involved in the generation of free amino acids, while arginyl aminopeptidase would mostly generate arginine and lysine (Toldrá 2002).

NUCLEOTIDE BREAKDOWN

The disappearance of ATP is very fast; in fact, it only takes a few hours to reach negligible levels. Many enzymes are involved in the degradation of nucleotides and nucleosides, as described in Chapter 15. The main changes in the nucleotide breakdown products occur during a few days postmortem, as shown in Figure 16.8. So, adenosine triphosphate (ATP), adenosine diphosphate, and adenosine monophosphate, which are intermediate degradation compounds, also disappear within 24 hours postmortem. Inosine monophosphate reaches a maximum by 1 day postmortem, but some substantial amount is still recovered after 7 days postmortem. On the other hand, inosine and hypoxanthine, as final products of these reactions, increase up to 7 days postmortem (Batlle et al. 2001).

GLYCOLYSIS

Glycolysis consists in the hydrolysis of carbohydrates, mainly glucose, either that remaining in the muscle or that formed from glycogen, to give lactic acid as the end product. As lactic acid
Figure 16.7. Example of the generation of some free amino acids during the processing of dry-cured ham (Adapted from Toldrá et al. 2000).

accumulates in the muscle, pH falls from neutral values to acid values around 5.3–5.8. The glycolytic rate, or speed of pH fall, depends on the animal species and the metabolic status. On the other hand, the glycolytic potential, which depends on the amount of stored carbohydrates, gives an indication of ultimate pH. The pH drop due to the lactic acid accumulation is perhaps the main consequence of glycolysis, and it has very important effects on meat processing because pH affects numerous chemical and biochemical (all the enzymes) reactions (Toldrá 2006a). There are many enzymes involved in the glycolytic chain; some of the most important are phosphorylase, phosphofructokinase, pyruvic kinase, and lactate dehydrogenase (Demeyer and Toldrá 2004). Lactate dehydrogenase is involved in the last step, which consists in the conversion of pyruvic acid into lactic acid. The contribution of glycolysis is restricted to a few hours postmortem, although it is also important in fermented meats where sugar is added for microorganism growth (see Chapter 18). The evolution of some glycolytic enzymes is shown in Figure 16.9.

LIPOLYSIS

Lipolysis makes an important contribution to the quality of meat products by the generation of free fatty acids, some of which have a direct influence on flavor, and others that, with polyunsaturations, may be oxidized to volatile aromatic compounds, acting as flavor precursors. The general scheme for lipolysis in muscle and adipose tissue is shown in Figure 16.10. In addition, the breakdown of triacylglycerols affects the texture of the adipose tissue, and an excess of lipolysis/oxidation may contribute to the development of rancid aromas or yellowish colors in fat (Toldrá 1998).

LIPOLYSIS IN AGED MEAT AND COOKED MEAT PRODUCTS

The relative amounts of released free fatty acids depends not only on the enzyme preference, but also on many other factors such as raw materials (especially affected by feed composition), type
Figure 16.8. Evolution of nucleotides and nucleosides during the aging of pork meat. (Adapted from Batlle et al. 2001.)
Figure 16.9. Evolution of β-glucuronidase and N-acetyl-β-glucosaminidase during the processing of a dry-fermented sausage (Toldrá, unpublished data).

of process, and extent of cooking (Toldrá 2002). The generation rate observed during in vitro incubations of muscle lipases with pure phospholipids is the following (in order of importance): linoleic > oleic > linolenic > palmitic > stearic > arachidonic acid. Lipolysis may also vary depending on the type of muscle, as oxidative and glucolytic muscles exhibit different lipase activity (Flores et al. 1996). The generation of free short-chain fatty acids is very low due to the lack of adequate substrate (Motilva et al. 1993b). Studies comparing pale, soft, exudative (PSE) versus normal pork reported that phospholipase A2 activity was higher and well correlated with the occurrence of the PSE syndrome (Chen et al. 2010). Reverse correlation was also reported for

the antioxidant activity of glutathione peroxidase (Chen et al. 2010). The physical and chemical conditions in the muscle and adipose tissue, especially during cooking, may affect the enzyme activity (see Tables 16.3 and 16.4). The evolution of muscle lipases during aging of pork meat is shown in Figure 16.11.

LIPOLYSIS IN FERMENTED MEATS

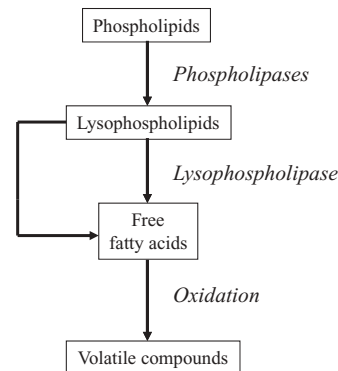
Depending on the raw materials, type of product, and processing conditions, the degree of contribution of endogenous and microbial origin lipases will vary (Toldrá 2007). The relative importance of both enzyme systems has been checked with mixtures of antibiotics and antimycotics used in sterile meat model systems (Molly et al. 1997). The results showed a minimal effect of antibiotics, and it was concluded that lipolysis is mainly brought about by muscle and adipose tissue lipases (60–80% of total free fatty acids generated), even though some variability might be found, depending on the batch and the presence of specific strains (Molly et al. 1997). Other authors have also observed that fatty acids are released in higher amounts when starters are added, but that there is significant lipolysis in the absence of microbial starters (Montel et al. 1993, Hierro et al. 1997). When pH drops during fermentation, the action of muscle lysosomal acid lipase and acid phospholipase becomes very important. Some strains are selected as starters based on their contribution to lipolysis. So, *Micrococcaceae* present a highly variable amount of extra- and intracellular lipolytic enzymes, dependent on the strain and type of substrate (Casaburi et al. 2008). The action of the extracellular enzymes on the hydrolysis of triacylglycerols becomes more important after 15–20 days of ripening (Ordoñez et al. 1999). Other microorganisms used as starters are *Staphylococcus warneri,* which gives the highest lipolytic activity, and


Figure 16.10. General scheme of lipolysis during the processing of meat and meat products.

Table 16.3. Physical Factors Affecting Lipolytic Activity During Meat and Meat Products Processing

Factor	Typical Trend	Effect on Lipolytic Enzymes
pH	Near neutral pH in dry-cured ham and cooked meat products.	Favors the activity of neutral lipase, neutral esterase and hormone-sensitive lipase.
	Slightly acid in aged meat	Favors the activity of lysosomal acid lipase, acid esterase and acid phospholipase
	Acid pH in dry-fermented sausages	Favors the activity of lysosomal acid lipase, acid esterase and acid phospholipase
Time	Short in aged meat, cooked meat products and fermented products	Short action for enough enzyme action but significant oxidation of the released fatty acids
	Medium in dry-fermented sausages and long in dry-cured ham	Time allows significant biochemical changes in dry sausages and very important in dry-cured ham
Temperature	High increase in cooking and smoking	Enzymes are strongly activated by cooking temperatures although for short time
	Mild temperatures in fermentation and dry-curing	Enzymes have time enough for its activity even though the use of mild temperatures. Lipases are active even during freezing storage of the raw meats
Water activity	Slightly reduced in cooked meats	Enzymes have very good conditions for activity
	Substantially reduced in dry-meats.	Muscle neutral lipase and esterases are affected. Rest of lipolytic enzymes remain unaffected by a_w drop
Redox potential	Anaerobic values in postmortem meat.	Slight effect on lysosomal acid lipase and phospholipase. More intense for rest of lipases

Staphylococcus saprophyticus; *S. carnosus* and *Staphylococcus xylosus* present poor and variable lipolytic activity (Montel et al. 1993). Lactic acid bacteria have poor lipolytic activity, mostly intracellular. Many molds and yeasts such as *Candida*, *Debaryomyces*, *Cryptococcus,* and *Trichosporum* have been isolated from fermented sausages, and all of them exhibit lipolytic activity (Ordoñez et al. 1999, Ludemann et al. 2004, Sunesen and Stahnke 2004).

The increases in the levels of free fatty acids show a great variability depending on the raw materials, type of sausage, and processing conditions (Toldrá et al. 2002). The increase may reach 2.5–5% of the total fatty acids, and the rate of release decreases in the following order: oleic > palmitic > stearic > linoleic (Demeyer et al. 2000). The release of polyunsaturated fatty acids from phospholipids is more pronounced during ripen-

ing (Navarro et al. 1997). Some short-chain fatty acids such as acetic acid may increase, especially during early stages of ripening. The generation of volatile compounds with impact on the aroma of fermented sausages depends on the type of processing and the starter culture added (Talon et al. 2002, Tjener et al. 2004). Some of the most important are aliphatic saturated and unsaturated aldehydes, ketones, methyl-branched aldehydes and acids, free short-chain fatty acids, sulfur compounds, some alcohols, terpenes (from spices), and some nitrogen-derived volatile compounds (Stahnke 2002).

LIPOLYSIS IN DRY-CURED HAM

The generation of free fatty acids in the muscle is correlated with the period of maximal phospholipid degradation (Motilva

Table 16.4. Chemical Factors Affecting Lipolytic Activity During Meat and Meat Products Processing

| Factor	Typical Trend	Effect on Lipolytic Enzymes
NaCl	Low in aged meat	No effect on enzyme activity
	Medium concentration in cooked meat products	Partial inhibition of muscle neutral lipase and esterases. Adipose tissue lipases not affected. Activation of lysosomal acid lipase and acid phospholipase
	High concentration in dry-cured hams	Slight activation of lysosomal acid lipase and acid phospholipase
Nitrate and nitrite	Concentration around 125 ppm in cured meat products	No significant effect
Ascorbic acid	Concentration around 500 ppm in cured meat products	Slight inhibition of all lipolytic enzymes
Glucose	Poor concentration in aged meat and dry-cured ham	No effect
	High concentration (up to 2 gL^{-1}) in fermented meats	No effect
Figure 16.11. Evolution of muscle lipases along the processing of dry-cured ham (Toldrá, unpublished data).

et al. 1993b, Buscailhon et al. 1994). Furthermore, a decrease in linoleic, arachidonic, oleic, palmitic, and stearic acids from phospholipids is observed at early stages of processing (Martin et al. 1999). This fact corroborates muscle phospholipases as the most important enzymes involved in muscle lipolysis. The amount of generated free fatty acids increases with aging time, up to 6 months of processing (see Fig. 16.12) and is higher in the external muscle *(Semimembranosus),* which contains more salt and is more dehydrated, than in the internal muscle *(Biceps femoris).* As lipase activity is mainly influenced by pH, salt concentration, and a_w (Motilva and Toldrá 1993), it appears that the observed lipid hydrolysis is favored by the same variables (salt increase and a_w reduction), as shown in Tables 16.3 and 16.4, that enhance enzyme activity in vitro (Vestergaard et al. 2000, Toldrá et al. 2004).

In the case of the adipose tissue, triacylglycerols form the major part of this tissue (around 90%) and are mostly hydrolyzed by neutral lipases to di- and monoacylglycerols and free fatty
Figure 16.12. Example of the generation of some free fatty acids in the adipose tissue during the processing of dry-cured ham (Adapted from Motilva et al. 1993b).

acids (see Fig. 16.12), especially up to 6 months of processing (Motilva et al. 1993a). Hormone-sensitive lipase was reported to be more stable than the adipose tissue neutral triglyceride lipase (Xiao et al. 2010). The amount of triacylglycerols decreases from about 90% to 76% (Coutron-Gambotti and Gandemer 1999). There is a preferential hydrolysis of polyunsaturated fatty acids, although some of them may not accumulate due to further oxidation during processing. Triacylglycerols that are rich in oleic and linoleic acids and are liquid at 14–18°C more hydrolyzed than triacylglycerols that are rich in saturated fatty acids such as palmitic acid and are solid at those temperatures (Coutron-Gambotti and Gandemer 1999). This means that the physical state of the triacylglycerols would increase the lipolysis rate by favoring the action of lipases at the water–oil interface. The rate of release of individual fatty acids is as follows: linoleic > oleic > palmitic > stearic > arachidonic (Toldrá 1992). The generation rate remains high up to 10 months of processing, when the accumulation of free fatty acids remains asymptotic or even decreases as a consequence of further oxidative reactions. Oleic, linoleic, stearic, and palmitic acids are those accumulated in higher amounts because they are present in great amounts in the triacylglycerols and have a better stability against oxidation. Similar results for generation of oleic, linoleic and palmitic acids were reported for Chinese Xuanwei ham (Xiao et al. 2010).

OXIDATIVE REACTIONS

The lipolysis and generation of free polyunsaturated fatty acids, susceptible to oxidation, constitute a key stage in flavor generation. The susceptibility of fatty acids to oxidation and the rate of oxidation depend on their unsaturation (Shahidi 1998a). So, linolenic acid (C 18:3) is more susceptible than linoleic acid (C 18:2), which is more susceptible than oleic acid (C 18:1). The animal species have different susceptibility to autoxidation in the following order: poultry > pork > beef > lamb (Tichivagana and Morrisey 1985). Oxidation has three consecutive stages (Shahidi 1998b). The first stage, initiation, consists in the formation of a free radical. This reaction can be enzymatically catalyzed by muscle lipoxygenase or chemically catalyzed by light, moisture, heat, and/or metallic cations. The second stage, propagation, consists in the formation of peroxide radicals by reaction of the free radicals with oxygen. When peroxide radicals react with double bonds, they form primary oxidation products, or hydroxyperoxides, that are very unstable. Their breakdown produces many types of secondary oxidation products by a free radical mechanism. Some of them *are* potent flavor-active compounds that can impart off-flavor to meat products during cooking or storage. The oxidative reactions finish by inactivation of free radicals when they react with each other (last stage). Thus, the result of these oxidative reactions consists in the generation of volatile compounds responsible of final product aroma. It is important to have a good control of these reactions because sometimes, oxidation may give undesirable volatile compounds with unpleasant off-flavors.

Muscle proteins may also experience some oxidative reactions during the processing of dry-cured ham. Dry-cured ham presented an intermediate oxidation when compared to

other dry-cured and cooked meat products when based on to-tal protein carbonyls and fluorescence corresponding to protein carbonyls. But a higher oxidation was reported in dry-cured ham when using α-aminoadipic semialdehyde and γ-glutamic semialdehyde as indicators of protein oxidation (Armenteros et al. 2009a).

OXIDATION TO VOLATILE COMPOUNDS

As mentioned previously, some oxidation is needed to gener-ate volatile compounds with desirable flavor properties. For in-stance, a characteristic aroma of dry-cured meat products is cor-related with the initiation of lipid oxidation (Buscailhon et al. 1994, Flores et al. 1998). However, an excess of oxidation may lead to off-flavors, rancidity, and yellow colors in fat.

The primary oxidation products, or hydroperoxides, are fla-vorless, but the secondary oxidation products have a clear contri-bution to flavor. There are a wide variety of volatile compounds formed by oxidation of the unsaturated fatty acids. The most important are (1) aliphatic hydrocarbons that result from autoxi-dation of the lipids; (2) alcohols, mainly originated by oxidative decomposition of certain lipids; (3) aldehydes, which can react with other components to produce flavor compounds; and (4) ketones produced through either β-keto acid decarboxylation or fatty acid β-oxidation. Other compounds, like esters, may contribute to characteristic aromas (Shahidi et al. 1987).

Oxidation rates may vary depending on the type of product or the processing conditions. For instance, TBA (thiobarbituric acid), a chemical index used as an indication of oxidation, in-creases more markedly in products such as Spanish chorizo than in French saucisson or Italian salami (Chasco et al. 1993). On the other hand, processing conditions such as curing or smoking also give a characteristic flavor to the product (Toldrá 2006b).

ANTIOXIDANTS

The use of spices such as paprika and garlic, which are rich in natural antioxidants, protects the product from certain oxida-tions. The same applies to antioxidants such as vitamin E that are added in the feed to prevent undesirable oxidative reactions in polyunsaturated fatty acids. Nitrite constitutes a typical curing agent that generally retards the formation of off-flavor volatiles that can mask the flavor of the product, and allows extended storage of the product (Shahidi 1998). Nitrite acts against lipid oxidation through different mechanisms: (1) binding of heme and prevention of the release of the catalytic iron, (2) binding of heme and nonheme iron and inhibition of catalysis, and (3) stabi-lization of lipids against oxidation. Smoking also contains some antioxidant compounds such as phenols that protect the external part of the product against undesirable oxidations. The muscle antioxidative enzymes also exert some contribution to the lipid stability against oxidation. In the case of fermented meats, the microbial enzyme catalase degrades the peroxides formed dur-ing the processing of fermented sausages (Toldrá et al. 2001). Thus, this enzyme contributes to stabilizing the color and fla-vor of the final sausage. Catalase increases its activity with cell growth to a maximum at the onset or during the stationary phase,

but it is mainly formed during the ripening stage. Large amounts of salt exert an inhibitory effect on catalase activity, especially at low pH values. The catalase activity is different depending on the strain. For instance, *S. carnosus* has a high catalase activ-ity in anaerobic conditions, while *S. warneri* has a low catalase activity (Talon et al. 1999).

Chemical and Biochemical Aspects of Color in Muscle-Based Foods

José Angel Pérez-Alvarez and Juana Fernández-López

Abstract: The term muscle-based foods encompass food products derived from cattle, hogs, poultry, fish, and shellfish. Various factors influence the quality of muscle food products during various handling, processing, and storage. In this regard, color plays a crucial role in consumers' perception and acceptance of muscle-based food products. The purplish-red to bright red color in muscle foods is due to the myoglobin pigment, and the postmortem changes in its color are useful indicators of the state of freshness of the source material. This chapter discusses various postmortem biochemical and related effects of the pigment in foods derived from these animals during processing and storage.

GENERAL ASPECTS OF MUSCLE-BASED FOOD COLOR

The first impression that a consumer receives concerning a food product is established visually, and among the properties observed are color, form, and surface characteristics.

All meats and muscle-based foods have a number of visually perceived attributes that contribute to their color and appearance as well as to their overall quality. According to Lozano (2006), the appearance can be divided in three different categories: color, cesia, and spatial properties or spatiality. Color is related to optical power spectral properties of the stimulus detected by observers (Hutchings 2002). Cesia include transparency, translucence, gloss, luster, haze, lightness, opacity, and matt, and is related to the properties of reflecting, transmitting, or diffusing light by foods evaluated by human observation. Spatial properties are divided in two main groups: (i) modes of appearance in which color is modified depending on the angle of observation related to the light incidence angle, such as metallic, pearlescent, or iridescent materials, and (ii) modes of appearance related to optical properties of surfaces or objects in which effects of ordered patterns (textures) or finishing characteristics of food (as roughness, polish, etc.) (Lozano 2006).

Color is the main aspect that defines a food's quality and a product may be rejected simply because of its color, even before other properties, such as aroma, texture, and taste, can be evaluated. This is why the appearance (optical properties, physical form, and presentation) of meat products at the sales point is of such importance for the meat industry (Lanari et al. 2002). As regards the specific characteristics that contribute to the physical appearance of meat and muscle-based foods, color is the quality that most influences consumer choice (Krammer 1994).

The relation between meat color and quality has been the subject of study since the 1950s since, indeed, Urbain (1952) described how consumers had learnt through experience that the color of fresh meat is bright red; and any deviation from this color (nonuniform or anomalous coloring) is unacceptable (Diestre 1992). The color of fresh meat and associated adipose tissue is, then, of great importance for its commercial acceptability, especially in the case of beef and lamb (Cornforth 1994) and in

---

certain countries like the United States and Canada, and there have been many studies to identify the factors controlling its stability. Adams and Huffman (1972) affirmed that consumers relate a meat's color with its freshness. In poultry, the consumers of many countries also associate the meat color with the way in which the animal was raised (intensive or extensive) and fed (cereals, animal feed, etc.).

Color as quality factor on meat can be appreciated in different ways in different countries, for example, in Denmark, pork meat color has the fifth place on consumers' purchase decision (Bryhni et al. 2002). Sensorial quality, especially color and appearance (Brewer and Mckeith 1999), of meat can be affected by internal and external factors.

Food technologists, especially those concerned with the meat industry, have a special interest in the color of food for several reasons. First, because of the need to maintain a uniform color throughout processing; second, to prevent any external or internal agent from acting on the product during processing, storage, and display; third, to improve or optimize a product's color and appearance; and lastly, to attempt bring the product's color into line with what the consumer expects.

Put simply, the color of meat is determined by the pigments present in the same. These can be classified into four types: biological (carotenes and hemopigments), which are accumulated or synthesized in the organism antemortem (Lanari et al. 2002); pigments produced as a result of damage during manipulation or inadequate processing conditions; pigments produced postmortem (through enzymatic or nonenzymatic reactions) (Montero et al. 2001); and finally, those resulting from the addition of natural or artificial colorants (Fernández-López et al. 2002).

As a quality parameter, color has been widely studied in fresh meat (MacDougall 1982, Cassens et al. 1995, Faustman et al. 1996) and cooked products (Anderson et al. 1990, Fernández-Ginés et al. 2003, Fernández-López et al. 2003a), while dry-cured meat products have received less attention (Pérez-Alvarez 1996, Pagán-Moreno et al. 1998, Aleson et al. 2003) because in this type of product color formation takes place during the different processing stages (Pérez Alvarez et al. 1997, Fernández-López et al. 2000, Pérez-Alvarez and Fernández-López 2009b); recently, new heme pigment has been identified in this type of products (Parolari et al. 2003, Wakamatsu et al. 2004a, 2004b).

From a practical point of view, color plays a fundamental role in the animal production sector, especially in meat production (beef and poultry, basically) (Zhou et al. 1993, Esteve 1994, Verdoes et al. 1999, Irie 2001), since in many countries of the European Union (Spain and Holland, for example) paleness receives a wholesale premium.

CHEMICAL AND BIOCHEMICAL ASPECTS OF COLOR IN MUSCLE-BASED FOODS

Of the major components of meat, proteins are the most important because they are only provided by essential amino acids (aa), which are very important for the organism's correct functioning, although they also make a technological contribution during processing, while some are also responsible for such important attributes as color. These are the so-called chromoproteins and they are mainly composed of a porphyrinic group conjugated with a transition metal, principally iron (metalloporphyrin), which forms conjugation complexes (heme group) (Whitaker 1972), this last being responsible for the color. However, other organic compounds exist alongside this, with isoprenoid-type conjugated systems (carotenes and carotenoproteins), also play an important part in meat color.

There are also some enzymatic systems whose coenzymes or prosthetic groups possess chromophoric properties (peroxidases, cytochromes, and flavins) (Faustman et al. 1996). However, their contribution to meat color is slight. In Section "Cytochromes", we describe the principal characteristics of the major compounds that impart color to meat.

Cytochromes

Cytochromes are metalloproteins with a prosthetic heme group, whose role in meat coloration is undergoing revision (Boyle et al. 1994, Faustman et al. 1996), since initially they were not thought to play a very important role (Ledwar 1984). These compounds are found in low concentrations in the skeletal muscle; in poultry, they do not represent more than 4.23% of the total hemeoproteines present (Pikul et al. 1986). The role of cytochrome (especially its concentration) in poultry meat color is fundamental, when the animal is previously exposed to stress (Ngoka and Froning 1982, Pikul et al. 1986). Cytochromes are most concentrated in cardiac muscle, so that when this organ is included in meat products, heart contribution to color must be taken into consideration, not to mention the reactions that take place during elaboration processes (Pérez-Álvarez et al. 2000b).

Carotenes

Carotenes are responsible for the color of beef, poultry meat and skin, fish and shellfish, in the latter case being of great economic importance. The color of the fat is also important in the carcasses grading. Also, carotenoids can be used as food coloring agents (Verdoes et al. 1999).

An important factor to be taken into account with these compounds is that they not synthesized by the animal's organism but by assimilation and during storage (Pérez-Álvarez et al. 2000b). On fat color, fatty acid composition can affect its color. When the ratio of cis-monounsaturated to saturated fatty acids is high, the fat exhibit a greater yellow color (Zhou et al. 1993). In the case of the carotenes present in fish tissues, these come from the ingestion of zooplankton and algae, and the levels are sometimes very high. The shell of many crustaceans also contains these compounds, for example, lobster (*Panilurus argus*).

The pigments responsible for color fish, particularly salmonids (trout, salmon among others), are astaxanthin and canthaxanthin, although they are also present in tunids and are one of the most important natural pigments of a marine origin.

In the case of shellfish, their color depends on the so-called carotenoproteins, which are proteins with a prosthetic group that may contain various types of carotene (Minguez-Mosquera 1997), which are themselves water soluble (Shahidi and Matusalach-Brown 1998).

In fish-derived products, the carotene content has previously been used as a quality parameter on its own; however, it has been demonstrated that this is not so and that other characteristics generally influence color (Little et al. 1979).

The carotene content and its influence on color is perhaps one of the characteristics that have received most attention (Swatland 1995). In the case of meat, especially beef, an excess of carotenes may actually lower the quality (Irie 2001), as occurs sometimes when classifying carcasses. The Japanese system for beef carcass classification classifies as acceptable fats with a white, slightly off-white, or slightly reddish-white color, while pink-yellowish and dark yellow are unacceptable (Irie 2001). It is precisely the carotenes that are responsible for these last two colorations.

However, in other animal species, such as chicken, the opposite effect is observed, since a high carotene (xanthophylls) concentration is much appreciated by consumers (Esteve 1994), yellow being associated with traditional or "home-reared" feeding (Pérez-Álvarez et al. 2000b).

The use of carotenoid canthaxanthin as a coloring agent in poultry feeds designed to result in the desired coloration of poultry meat skins. Although the carotenoids used mostly are citranaxanthin, capsanthin, and capsorubin, canthaxanthin shows superior pigmenting properties and stability during processing and storage (Blanch 1999). Zhu et al. (2009) reported that dietary supplementation with *Lactobacillus salivarius* increased the xanthophyll concentration in tissue and the Roche color fan scores of the shank skin of chickens.

Farmed fish, specially colored fish (salmon, rainbow trout, for example), is now of the main industries, for example, Norway exports a great part of its salmon. To improve its color and brilliance, 0.004–0.04 weight% proanthocyanidin is added to fish feed containing carotenoids (Sakiura 2001). For rainbow trout, carotenoid concentrations could be 10.7 or 73 mg/kg canthaxanthin, or 47 or 53 mg/kg astaxanthin.

HEMOPROTEINS

Of the hemoproteins present in the muscle postmortem, myoglobin (Mb) is the one mainly responsible for color, since hemoglobin (Hb) arises from the red cells that are not eliminated during the bleeding process and are retained in the vascular system, basically in the capillaries (incomplete exsanguination, the average amount of blood remaining in meat joints being 0.3%) (Warris and Rodes 1977). However, their contribution to color does not usually exceed 5% (Swatland 1995). There was wide variation in amounts of Hb from muscle tissue of bled and unbled fish. Mb content was minimal as compared to Hb content in fish light muscle and white fish whole muscle. Hb made up 65% and 56% of the total hem protein by weight in dark muscle from unbled and bled fish (Richards and Hultin 2002).

Mb, on average, represents 1.5% in weight of the proteins of the skeletal muscle, while Hb represents about 0.5%, the same as the cytochromes and flavoproteins together. Mb is an intracellular (sarcoplasmic) pigment apparently distributed uniformly within muscles (Ledwar 1992, Kanner 1994). It is red in color and water soluble and is found in the red fibers of both vertebrates and invertebrates (Knipe 1993, Park and Morrisey 1994), where it fulfils the physiological role of intervening in the oxidative phosphorylation chain in the muscle (Moss 1992).

STRUCTURE OF MYOGLOBIN

Structurally, Mb can be described as a monomeric globular protein with a very compact, well-ordered structure that is specifically, almost triangularly, folded and bound to a hemo group (Whitaker 1972). It is structurally composed of two groups: a proteinaceous group and a heme group.

The protein group has only one polypeptide chain composed of 140–160 amino acid residues, measuring 3.6 nm and weighing 16,900 Da in vertebrates (Lehningher 1981). It is composed of eight relatively straight segments (where 70% of the aa is found), separated by curvatures caused by the incorporation in the chain of proline and other aa that do not form α-helices (such as serine and isoleucine). Each segment is composed of a portion of α-helix, the largest of 23 aa and the shortest of 7 aa, all dextrogyrating.

The high helicoidal content (forming an ellipsoid of 44 × 44 × 25 Å) and the lack of disulphide bonds (there is no cysteine) means that Mb is an atypical globular protein. The absence of these groups makes the molecule highly stable (Whitaker 1972). Although the three-dimensional structure seems irregular and asymmetric, it is not totally anarchic, and all the molecules of Mb have the same conformation.

One very important aspect of the protein part of Mb is its lack of color. However, the variations presented by its primary structure and the aa composition of different animal and fish species destined for human consumption are the cause of the different colorations of meat and their stability when they are not displayed in the same conditions (Lorient 1982, Lee et al. 2003).

The heme group of Mb (as in Hb and other proteins) is, as mentioned in the preceding text, a metalloporphyrin. These molecules are characterized by their high degree of coloration as a result of their conjugated cyclic tetrapyrrole structure (Kalyanasundaram 1992). The heme group is composed of a complex, organic annular structure, protoporphyrin, to which an iron atom in ferrous state is united (Fe II). This atom has six coordination bonds, four with the flat protoporphyrin molecule (forming a flat square complex) and two perpendiculars to it. The sixth bond is open and acts as a binding site for the oxygen molecule.

Protoporphyrin is a system with a voluminous flat ring composed of four pyrrole units connected by methyl bridges (= C-). The Fe atom with a coordination number of six lies in the center of the tetrapyrrole ring and is complexed to four pyrrolic nitrogen's. The heme group is complexed to the polypeptide chain

(globin) through a specific histidine residue (imadazole ring) occupying the fifth position of the Fe atom (Dadvison and Henry 1978).

The heme group is bound to the molecule by hydrogen bridges that are formed between the propionic acid side chains and other side chains. Other aromatic rings exist near, and almost parallel to, the heme group, which may also form pi (π) bonds (Stauton-West et al. 1969).

The Hb contains a porphyrinic heme group identical to that of Mb and equally capable of undergoing reversible oxygenation and deoxygenation. Indeed, it is functionally and structurally paired with Mb and its molecular weight is four times greater, since it contains four peptidic chains and four heme groups. The Hb, like Mb, has its fifth ligand occupied by the imadazole group of a histidine residue, while the sixth ligand may or may not be occupied. It should be mentioned that the fifth and sixth positions of other hemoproteins (cytochromes) are occupied by R groups of specific aa residues of the proteins and, therefore, cannot bind to oxygen (O_2), carbon monoxide (CO), or cyanide (CN^-), except a_3, which, in its biological role, usually binds to oxygen.

One of the main differences between fish and mammalian is that fish Mb had two distinct endothermic peaks indicating multiple states of structural unfolding, whereas mammalian Mb followed a two-state unfolding process. Changes in α-helix content and tryptophan fluorescence intensity with temperature were greater for fish Mb than for mammalian Mb. Fish Mb show labile structural folding, suggesting greater susceptibility to heat denaturation than that of mammalian Mb (Saksit et al. 1996).

Helical contents of frozen-thawed Mb were practically the same as those of unfrozen Mb, regardless of pH. Frozen-thawed Mb showed a higher autoxidation rate than unfrozen Mb. During freezing and thawing, Mb suffered some conformational changes in the no helical region, resulting in a higher susceptibility to both unfolding and autoxidation (Chow et al. 1989). In tuna fish Mb, its stability was in the order bluefin tuna (*Thunnus thynnus*) > yellowfin tuna (*Thunnus albacares*) > bigeye tuna (*Thunnus obesus*), with autoxidation rates in the reverse order. The pH dependency of Mb from skipjack tuna (*Katsuwonus pelamis*) and mackerel (*Scomber scombrus*) were similar. Lower Mb stability was associated with higher autoxidation rate (Chow 1991).

CHEMICAL PROPERTIES OF MYOGLOBIN

The chemical properties of Mb center on its capacity to form ionic and covalent groups with other molecules. Its interaction with several gases and water depends on the oxidation state of the Fe of the heme group (Fox 1966), since this may be either in its ferrous (Fe II) state or in ferric (Fe III) state. Upon oxidation, the Fe of the heme group takes on a positive charge (Kanner 1994) and, typically, binds with negatively charged ligands, such as nitrites, the agents responsible for the nitrosation reactions in cured meat products.

When the sixth coordination ligand is free, the Mb is usually denominated deoxymyoglobin (DMb), which is purple in color.

However, when this site is occupied by oxygen, a noncovalent complex is formed between this gas and the Mb, and it is denominated oxymyoglobin (OMb), which is cherry or bright red (Lanari and Cassens 1991). When the oxidation state of the iron atom is modified to the ferric state, the sixth position is occupied by a molecule of water; it is denominated metmyoglobin (MMb), which is brown.

Mb absorbs light in the ultraviolet region and through practically the complete visible region of light (Fox 1966). MMb, OMb, nitrosomyoglobin (NOMb), and DMb have maximum absorbance's (>400 nm) at about 410, 418, 419, and 434 nm, respectively (Millard et al. 1996). The absorbance band is typically much weaker at higher wavelengths (500–600 nm). Above 500 nm, OMb and NOMb have absorption maxima at around 545 and 585 nm both. The NOMb complex maintains Mb in ferrous state, but is somewhat unstable and can be displaced and oxidized if stored with excess oxygen and light (Kanner 1994).

There are several possible causes for MMb to be generated, and these may be due to the ways in which tunids, meat, and meat products are obtained, transformed, or stored (MacDougall 1982, Lee et al. 2003, Mancini et al. 2003). Among the most important factors are: low pH, the presence of ions and high temperatures during processing (Osborn et al. 2003), the growth and/or formation of metabolites from the microbiota (Renerre 1990), the activity of endogenous reducing enzymes (Arihara et al. 1995, Osborn et al. 2003), the levels of endogenous (Lanari et al. 2002) or exogenous antioxidants, such as ascorbic acid or its salts, tocopherols (Irie et al. 1999) or plant extracts (Fernández-López et al. 2003b, Sánchez-Escalante et al. 2003).

This change in the oxidation state of the heme group will result in the group being unable to bind with the oxygen molecule (Arihara et al. 1995).

DMb is able to react with other molecules to form colored complexes, many of which are of great economic relevance for the meat industry. The most characteristic example is the reaction of DMb with nitrite, since its incorporation generates a series of compounds with distinctive colors: red in dry-cured meat products or pink in heat-treated products. The products resulting from the incorporation of nitrite are denominated cured, and such products are of enormous economic importance worldwide (Pérez-Alvarez 1996).

The reaction mechanism is based on the property of nitric oxide (NO, generated in the reaction of nitrite in acid medium that readily gives up electrons) to form strong coordinated covalent bonds, which form an iron complex with the heme group without the oxidation state of its structure having any influence. The compound formed after the nitrification reaction is denominated NOMb.

As mentioned in the preceding text, the presence of reducing agents such as hydrosulfhydric acid (H_2S) and ascorbates, lead to the formation of undesirable pigments both in meat and meat products. These green pigments are called sulphomyoglobin (SMb) and colemyoglobin (ColeMb), respectively, and are formed as a result of bacterial activity and by an excess of reducing agents in the medium. The formation of SMb is reversible, but that of ColeMb is an irreversible mechanism, since

it is rapidly oxidized between pH 5 and 7, releasing the different parts of the Mb (globin, iron, and the tetrapyrrole ring).

From a chemical point of view, it should be borne in mind that the color of Mb, and therefore of the meat or meat products, not only depends on the molecule that occupies the sixth coordination site, but also the oxidation state of the iron atom (ferrous or ferric), the type of bond formed between the ligand and the heme group (coordinated covalent, ionic, or none) and the state of the protein (native or denaturalized form), not to mention the state of the porphyrin of the heme group (intact, substituted or degraded) (Pérez-Alvarez 1996).

During heat treatment of fish flesh, aggregation of denatured fish proteins is generally accompanied by changes in light scattering intensity. Results demonstrate the use of changes in relative light scattering intensity for studying structural unfolding and aggregation of proteins under thermal denaturation (Saksit et al. 1998). When fatty fish meat like *Trachurus japonicus* was heat treated, MMb content increased linearly, and the percentages of denatured Mb and apomyoglobin increased rapidly when mince was exposed to heat, but when temperature reach 60°C, the linearity is broken. Results indicated that stability of the color was higher than that of Mb and that the thermal stability of heme was higher than that of apomyoglobin (Hui et al. 1998).

Both Mb and ferrous iron accelerated lipid oxidation of cooked water-extracted fish meat. EDTA inhibited the lipid oxidation accelerated by ferrous iron, but not that accelerated by Mb. Also, with cooked nonextracted mackerel meat, EDTA noticeably inhibited lipid oxidation. Nonheme iron-catalysis seemed to be related in part to lipid oxidation in cooked mackerel meat. Addition of nitrite in combination with ascorbate resulted in a marked inhibition of lipid oxidation in the cooked mackerel meat. From these results, it was postulated that nitric oxide ferrohemochromogen, formed from added nitrite and Mb, present in the mackerel meat in the presence of a reducing agent, possesses an antioxidant activity, which is attributable in part to the function as a metal chelator (Ohshima et al. 1988).

Tuna fish meat can be improved in its color when the flesh is treated with CO. The specific spectrum of carboxymyoglobin (COMb) within the visible range can be obtained. Penetration of CO into tuna muscle was very slow. After approximately 1–4 hours CO had penetrated 2–4 mm under the surface, and after 8 hours, CO had penetrated 4–6 mm. Mb extracts from tuna muscle treated with CO exhibited higher absorbance at 570 than at 580 nm (Chau et al. 1997). Jayasingh et al. (2001) reported that CO (0.5%) can penetrate to a depth of 15 mm (1 week) in ground beef. These authors also mentioned that when COMb is exposed to atmospheres free of CO, COMb slowly dissociate from Mb.

In dry-cured meat products, as Parma ham (produced without nitrite or nitrate), the characteristic bright red color (Wakamatsu et al. 2004a) is caused by Zn-protoporphyrin IX (ZPP) complex, a heme derivative. This type of pigment can be formed by endogenous enzymes as well as microorganisms (Wakamatsu et al. 2004b). Spectroscopic studies of Parma ham during processing all process, revealed a gradual transformation of muscle Mb, initiated by salting and continuing during aging. Pigments became increasingly lipophilic during processing, suggesting that

a combination of drying and maturing yields a stable red color (Parolari et al. 2003). Electron spin resonance spectra showed that the pigment in dry-cured Parma ham is at no stage a nitrosyl complex of ferrous Mb as found in brine-cured ham and Spanish Serrano hams (Moller et al. 2003). These authors also establish that heme moiety is present in the acetone/water extract and that Parma ham pigment is gradually transformed from an Mb derivative into a nonprotein heme complex, thermally stable in acetone/water solution. Adamsen et al. (2003) also demonstrated that the heme moieties of Parma ham pigments have also antioxidative properties.

COLOR CHARACTERISTICS OF BLOOD PIGMENTS

Hb has function carrying oxygen to the tissues. Thus, the oxygenated hemoglobin $Hb(Fe(II))O_2$ is a very stable molecule but does slowly auto-oxidize at a rate of about 3% per day. This rate is accelerated at lower oxygen tensions if the Hb is partially oxygenated. The "blood pigments" chemistry is actually quite complex (Umbreit 2007).

Nagababu and Rifkind (2000) reported that the auto-oxygenation generates $Hb(Fe(III))$, called methemoglobin (MHb), and superoxide. At least in vitro, the superoxide undergoes dismutation to hydrogen peroxide and oxygen. The hydrogen peroxide is rapidly decomposed by catalase. The sixth coordinate of the MHb is occupied with water. If not immediately destroyed, the hydrogen peroxide would react with $Hb(Fe(II))O_2$ to produce ferrylhemoglobin, $Hb(Fe(IV)) = O$, with a rhombic heme that reacts with further hydrogen peroxide to produce free Fe(III) and porphyrin degradation products.

Jaffe (1981) reported that the MHb can be reduced by the NADH-cytochrome b5-MHb reductase or by direct reduction by ascorbate and glutathione.

The Hb can react with nitrites; the reaction with oxyhemoglobin (OHb) limits the half-life of the NO. The reaction with free Hb is so fast that any NO is consumed immediately (Vaughin et al. 2000, Huanf et al. 2001). According to Umbreit (2007), there are two major reactions of the nitrogenous compounds with Hb Fe(II), one binding NO to the heme and the other reducing nitrite to NO.

Muscles can retain several amounts of blood. Thus, Richard et al. (2005) reported that dark muscle from Atlantic mackerel contained roughly equal amounts of Hb and Mb, although in other fish species such as bluefin tuna (*T. thynnus*) Hb can be the major heme compound in dark muscle "sangacho" (Sánchez-Zapata et al. 2009a). Niewiarowicz et al. (1986) reported that in different poultry dark meat species the ratio between Hb and Mb varies from 20% to 40%. In mammals, this ratio has been reported to range from 7% to 35% (Han et al. 1994).

Animal blood is little used in the food industry, because of dark color it imparts to the products to which it is added. Attempts to solve food color related problems have employed several different processes and means, but they are not always completely satisfactory. The addition of 12% blood plasma to meat sausages lead to pale-colored products. Another means of solving color problems is the addition of discolored whole blood or globin by

eliminating Hb's heme group. From blood, natural red pigments can be obtained without using coloring agents such as nitrous acid salts; these pigments have zinc protoporphyrin as the metalloporphyrin moiety, and can be used in producing beef products, whale meat products, and fish products (including fish pastes), and a favorable color (Numata and Wakamatsu 2003).

There was wide variation in amounts of Hb extracted from muscle tissue of bled and unbled fish, and the residual level in the muscle of bled fish was substantial. Mb content was minimal as compared to Hb content in mackerel light muscle and trout whole muscle. Hb made up 65% and 56% of the total heme protein by weight in dark muscle from unbled and bled mackerel. That blood-mediated lipid oxidation in fish muscle depends on various factors, including Hb concentration, Hb type, plasma volume, and erythrocyte integrity (Richards and Hultin 2002).

Alvarado et al. (2007) reported that the Hb content can vary a lot among animal species and muscle types; it is clear that the Hb levels present in muscle-based foods have the potential to substantially contribute to lipid oxidation. Also, the presence of blood, Mb, Fe^{2+}, Fe^{3+}, or Cu^{2+} can stimulate lipid oxidation in the fillets of ice-fish (Rehbein and Orlick 1990).

The formation of ferryl and/or perferryl species upon reaction with hydrogen peroxide or lipid hydroperoxides has been reported to be either truly initiators or important catalysts of lipid oxidation in raw muscle meat products (Baron and Andersen 2002). Various factors such as the ability of the Hb to auto-oxidize and release of hematin, the heme–iron moiety nonbound to the protein, have also been reported to be crucial in promoting lipid oxidation (Grunwald and Richards 2006).

As was mentioned in the preceding text, blood utilization by the food industry is minimal, but many blood sausages are elaborated around the world (Diez et al. 2009). Problem associated with blood uses is discoloration through the disruption of the heme group of the Hb moiety. Several attempts are made to find a possible solution to the color problems caused by blood addition, one of them is the Hb moiety conversion into the more stable and sensorial accepted carboxyhaemoglobin (COHb) by saturation with carbon monoxide (CO). This pigment is very stable and can be visualized by the reflectance spectra (400–700 nm) (Fontes et al. 2010).

Fontes et al. (2010) reported differences between the spectra of blood CO-treated and its untreated counterpart. When CO was bubbled into the blood samples, the spectra reflected the COHb color properties in the red region, whose maximum reflectance occurs at 700 nm. Greater color stability was also observed in CO-treated sample as indicated by small differences between reflectance curves.

In adipose tissues, residual Hb is associated with the presence of capillaries or with hemorrhage. Irie (2001) reported that internal fat is whiter, with less Hb and with harder fat, than subcutaneous fat. The Hb derivatives are MHb, OHb, and deoxyhemoglobin (DHb). This Hb derivatives show different reflectance and absorbance spectra in which each showed different absorbance bands (AB); thus, MHb showed AB at 406, 500, and 630 nm; OHb showed 418, 540–542, 516–578, 950 nm; and DHb showed 430, 555, 760, and 910 nm.

From technological point of view, COMb can be used in several types of meat processing; thus, CO can be used in (i) modified atmosphere packaging of several type of meats (Raines and Hunt 2010), (ii) pasteurized meat products (Fontes et al. 2004), (iii) dry blood (Fontes et al. 2010), and (iv) combination with injection-enhancement ingredient (lactate) for beef color stabilization (Suman et al. 2010). But several legal problems are associated with its use; thus, the industry must avoid its use to rejuvenate the color of spoiled meat.

Stiebing (1990) reported that during cooking, the oxygen partial pressure in blood sausages decreases to a point where oxidation occurs, instead of oxygenation. But the CO-treated blood can increase shelf life (refrigerated storage, 4 days).

FAT COLOR

From a technological point of view, fat fulfils several functions, although as regards color, its principal role is in the brightness of meat products. Processes such as "afinado" during the elaboration of dry-cured ham involve temperatures at which fat melts, so that it infiltrates the muscle mass and increases the brilliance (Sayas 1997). When the fat is finely chopped, it "dilutes" the red components of the color, thus decreasing the color intensity of the finished product (Pérez-Alvarez et al. 2000). However, fats do not play such an important role in fine pastes because, after emulsification, the fat is masked by the matrix effect of the emulsion, so that it contributes very little to the final color.

The color of fat basically depends on the feed that the live animal received (Esteve 1994, Irie 2001). In the case of chicken and ostrich, the fat has a "white" appearance (common in Europe) when the animal has been fed with "white" cereals or other ingredients not containing xanthophylls, since these are accumulated in subcutaneous fat and other fatty deposits. However, when the same species are fed on maize (rich in xanthophylls), the fatty deposits take on a yellow color.

Beef or veal fat that is dark, hard (or soft), excessively bright or shiny lowers the carcass and cut price. Fat with a yellowish color in healthy animals reflects a diet containing beta-carotene (Swatland 1988). While fat color evaluation has traditionally been a subjective process, modern methods include such techniques as optical fiber spectrophotometry (Irie 2001).

Another factor influencing fat color is the concentration of the Hb retained in the capillaries of the adipose tissues (Swatland 1995). As in meat, the different states of Hb may influence the color of the meat cut. OMb is responsible for the yellowish appearance of fat, since it affects different color components (yellow-blue and red-green).

The different states of Hb present in adipose tissue may react in a similar way as in meat, so that fat color should be measured as soon as possible to avoid possible color alterations.

When the Hb in the adipose tissue reacts with the nitrite incorporated in the form of salt, nitrosohemoglobin (NOHb) is generated, a pigment that imparts a pink color to the fat. This phenomenon occurs principally in dry-cured meat products with a degree of anatomical integrity, such as dry-cured ham or shoulder (Sayas 1997).

When fat color is measured, its composition should be kept in mind, since its relation with fatty acids modifies its characteristics, making it more brilliant or duller in appearance. The fat content of the conjunctive tissue must also be borne in mind, since collagen may present a glassy appearance because, at acidic pH, it is "swollen", imparting a transparent aspect to the product.

REDUCED NITRITE MEAT PRODUCTS

Health concerns relating to the use of nitrates and nitrites in cured meats (cooked and dry cured) have led to a tendency toward decreased usage to alleviate the potential risk of the formation of carcinogenic, teratogenic, mutagenic *N*-nitroso compounds (Karolyi 2003), cytotoxic effects of nitrosamines and by the toxic effects of nitrite per se (metmyoglobinaemia and fall of blood pressure). But it is well known that nitrate/nitrite is widely used as a curing agent in the meat industry, although in recent years its omission from meat processing has been proposed (Viuda-Martos et al. 2009a).

Meat scientists have to take into account that any technological strategy (Pérez-Alvarez 2008) or the use of other ingredients (meat, nonmeat, and functional ingredients) can modify color characteristics (Pérez-Alvarez and Fernández-López 2009a, Sánchez-Zapata et al. 2009b).

As soon as nitrite is added in the meat formulation, it starts to disappear (nitrite is reduced to nitric oxide (NO)) that reacts with Mb to form NO-OMb and often can no longer be detected analytically at a later time. The rate of depletion is dependent on various factors, such as pH, initial nitrite concentration, processing and storage temperatures, meat-to-water ratio, and the presence of reductants (Pérez-Alvarez et al. 1993).

According to Pérez-Alvarez (2006), two-thirds of the Mb present in the meat is transformed into NOMb, although it is possible that only 50% of the Mb reacts. The rest corresponds to the residual nitrite. Residual nitrite levels (10–20% of the originally added sodium nitrite) correspond to nitrite that has not reacted with Mb and it is available for other reactions in the organism (Fernández-López et al. 2007).

Recently, it has been found that plants and their extracts can be used as indirect sources of nitrate (Shahid-Umar and Iqbal 2007, Shahid-Umar et al. 2007, Parks et al. 2008) in the production of meat products (Sebranek and Bacus 2007a, 2007b).

Six "technological" pathways exist for reducing the nitrite present in the meat products:

1. Exposure to γ radiation, as described by Wei et al. (2009).
2. Reaction with compounds of a polyphenolic nature (Garrote et al. 2004) derived basically from spices added in the formulation of the meat products. Also, can react with polyphenols, mainly hydroxycinnamic acids, like caffeic or ferulic acid, or with glycosylated flavanones, like hesperidin or narirutin, that are natural compounds of citrus coproducts (Viuda-Martos et al. 2010a).
3. Reaction with reducing agents present in the formulation or with endogenous substances. For example, when the pH of the meat is less than six, the nitrite added or that arising from the microbial reduction of nitrates is transformed

into nitrous acid (relatively unstable). This, in turn, reacts with endogenous (cysteine, reduced nicotinamide adenine dinucleotide, cytochromes, and quinines) or exogenous (ascorbic acid and its salts) reducing substances of the meat and is transformed into NO, completing the dismutation reaction, as described by Pérez-Alvarez (2006).
4. Action of bacteria with nitrite-reductase activity such as *Staphylococcus carnosus*, *Staphylococcus simulans*, or *Staphylococcus saprophyticus* (Gøtterup et al. 2007). The action mechanism through which strains of *Staphylococcus* use nitrate/nitrite is thought to be related with its capacity to act as alternative electron acceptor in the cell respiratory chain (Gøtterup et al. 2008). The synthesis of nitrite reductases only occurs in anaerobic conditions and is induced by the presence of nitrate or nitrite in the medium (Neubauer and Götz 1996).
5. Combined method, reducing the quantity of residual nitrite by interaction with natural ingredients (tomato paste, annatto). Thus, Deba et al. (2007) reported that the addition of tomato paste to frankfurters reduces the added nitrite level from 150 to 100 mg/kg without any negative effect on the processing and quality characteristics of the product during storage.
6. Reaction with compounds present in citric coproducts such as orange and lemon albedo (Aleson-Carbonell et al. 2003, Fernández-Ginés et al. 2004), orange dietary fiber (Fernández-López et al. 2008b, 2009), citrus fiber washing water (Viuda-Martos et al. 2009b), orange fiber plus essential oils (Viuda-Martos et al. 2010a, 2010b).

ALTERATIONS IN MUSCLE-BASED FOOD COLOR

The color of meat and meat products may be altered by several factors, including exposure to light (source and intensity), microbial growth, rancidity, and exposure to oxygen. Despite the different alterations in color that may take place, few have been studied, including the pink color of boiled uncured products, premature browning (PMB), and melanosis in crustaceans.

PINK COLOR OF UNCURED MEAT PRODUCTS

The normal color of a meat product that has been heat treated but not cured is "brown," although it has recently been observed that these products show an anomalous coloration (red or pink) (Hunt and Kropf 1987). This problem is of great economic importance in "grilled" products, since this type of color is not considered desirable.

This defect may occur both in meats with a high hemoprotein content such as beef and lamb (red) and in those with a low concentration, including chicken and turkey (pink) (Conforth et al. 1986).

One of the principal causes of this defect is the use of water rich in nitrates, which are reduced to nitrites by nitrate-reducing bacteria, which react with the Mb in meat to form NOMb (Nash et al. 1985). The same defect may occur in meat products containing paprika, which, according to Fernández-López (1998),

contains nitrates that, once incorporated in the product, may be similarly reduced by the microorganisms. Conforth et al. (1991) mentions that several nitrogen oxides may be generated in gas and electric ovens used for cooked ham and that these will react with the Mb to generate nitrosohemopigments. Also produced in ovens is CO, which reacts with Mb during thermal treatment to form a pink-colored pigment, carboxyhemochrome. It has also been described how the use of adhesives formed from starchy substances produces the same undesirable color in cooked products (Scriven et al. 1987).

The same anomalous color may be generated when the pH of the meat is high (because of the addition of egg albumin to the ingredients) (Froning et al. 1968) and when the cooking temperature during processing is too low. These conditions favor the development of a reducing environment that maintains the iron of the Mb in its ferrous form, imparting a reddish/pink color (as a function of the concentration of hemopigments) instead of the typical grayish-brown color of heat-treated uncured meat products.

Cooking uncured meat products, such as roast beef, at low temperatures (less than 60°C) may produce a reddish color inside the product, which some consumers may like. This internal coloring is not related with the formation of nitrosopigments, but results from the formation of OMb, a phenomenon that occurs because MMb-reducing enzymatic systems exist in the muscle that are activated at temperatures below 60°C (Osborn et al. 2003).

Microbial growth may also cause the formation of a pink color in cooked meats, since these reduce the oxido-reduction potential of the product during their growth. This is important when the microorganisms that develop in the medium are anaerobes, since they may generate reducing substances that reduce the heme iron. When extracts of *Pseudomonas* cultures are applied, the MMb may be reduced to Mb (Faustman et al. 1990). Recently, Gallego-Restrepo et al. (2010) reported that microorganism can play an important role in the color of uncured meat products during its elaboration process. These authors recommended the use of microbiological starter culture with a higher metabolic action at refrigeration conditions to obtain excellent color characteristics on this type of products.

Melanosis

Melanosis or blackspot, involving the appearance of a dark, even black, color, may develop post mortem in certain shellfish during chilled and frozen storage (Slattery et al. 1995). Melanosis is of huge economic importance, since the coloration may suggest a priori in the eyes of the consumer that the product is in bad condition, despite the fact that the formation of the pigments responsible involves no health risk.

Melanosis is an objectionable surface discoloration of high valuable shellfish as lobsters caused by enzymic formation of precursors of phenolic pigments. Blackspot is a process regulated by a complex biochemical mechanism, whereby the phenols present in a food are oxidized to quinones in a series of enzymatic reactions caused by polyphenoloxidase (PO) (Ogawa et al. 1984). This is followed by a polymerization reaction, which

produces pigments of a high molecular weight and dark in color. Melanosis is produced in the exoskeleton of crustaceans, first in the head and gradually spreading toward the tail. Melanosis of shell and hyperdermal tissue in some shellfish as lobsters was related to stage of molt. The molting fluid is considered as the source of the natural activator(s) of pro-PO. Polyphenol oxidase (catechol oxidase) can be isolated from shellfish cuticle (Ali et al. 1994) and still active during iced or refrigerated storage. The process can be controlled by using sulfites (Ferrer et al. 1989), although their use is prohibited in many countries. Also ficin (Taoukis et al. 1990), 4-hexylresorcinol, functioned as a blackspot inhibitor, alone and in combination with L-lactic acid (Benner et al. 1994). Recently, Encarnacion et al. (2010) reported that dietary supplementation of the *Flammulina velutipes* mushroom extract in shrimp could be a promising approach to control postmortem development of melanosis and lipid oxidation in shrimp muscles.

Premature Browning

Hard-to-cook patties show persistent internal red color and are associated with high pH (>6) raw meat. Pigment concentration affects red color intensity after cooking (residual undenatured Mb), so this phenomenon is often linked to high pH dark-cutting meat from older animals. PMB is a condition in which ground beef (mince) looks well done at lower than expected temperature (Warren et al. 1996).

PMB of beef mince is a condition in which Mb denaturation appears to occur on cooking at temperature lower than expected and, therefore, may indicate falsely that an appropriate internal core temperature of 71°C has been achieved (Suman et al. 2004). The relationship between cooked color and internal temperature of beef muscle is inconsistent and depends on pH and animal maturity. Increasing the pH may be of benefit in preventing PMB but may increase incidence of red color in well-cooked meat (cooked over internal temperature of 71.1°C) (Berry 1997). When PSE meat is used in patties processing and those containing OMb easily exhibited PMB. One of the reasons of this behavior is that percentage of Mb denaturation increased as cooking temperature increased (Lien et al. 2002). Recently, Mancini et al. (2010) reported that the use of several additives such as lactate improved raw color stability, but did not minimize PMB.

COLOR AND SHELF LIFE OF MUSCLE-BASED FOODS

Meat and meat products are susceptible to degradation during storage and throughout the retail process. In this respect, color is one of the most important quality attributes for indicating the state of preservation in meat.

Any energy received by food can initiate its degradation, the rate of any reactions depending on the exact composition of the product (Jensen et al. 1998), environmental factors (light, temperature, presence of oxygen), or the presence of additives.

Transition metals, such as copper or iron, are very important in the oxidative/antioxidative balance of meat. When the

free ions of these two metals interact, they reduce the action of certain agents, such as cysteine, ascorbate and α-tocopherol, oxidizing them and significantly reducing the antioxidant capacity in muscle (Zanardi et al. 1998).

The iron in meat is 90% heme iron (HI), which is several times more absorbable than nonheme iron (NHI) present in other foods (Fernández-López et al. 2008a). Although the mechanism for heme iron release in meat has not been determined, oxidation of the porphyrin ring and denaturation of Mb (Kristensen and Purslow 2001) are probably involved.

Harel et al. (1988) reported that the interaction of MMb with H_2O_2 or lipid hydroperoxide results in the release of free ionic iron. Free ionic iron can serve as a catalyst in the production of àOH from H_2O_2 as well as in the degradation of lipid hydroperoxides to produce peroxyl and alkoxyl radicals, which can initiate lipid oxidation and/or be self-degraded to the secondary products of lipid oxidation (Min and Ahn 2005). However, reducing compounds are essential to convert ferric to ferrous ion, a catalyst for Fenton reaction.

Lee et al. (1998) reported that during refrigerated storage of meat, there is a release of iron from the heme group, with a consequent increase in NHI, which speeds up lipid oxidation. Also, the heme molecule can break down during cooking or storage (Gómez-Basauri and Regenstein 1992a, 1992b, Miller et al. 1994a, 1994b) and can generate NHI. The increase of NHI in meats and fish is considered to be a reflection of the decrease of HI and is linked to the oxidative deterioration (Schricker and Miller 1983).

Nonheme iron is considered the most important oxidation promoter in meat systems, and therefore, knowledge of the proportions of the chemical forms of iron is of great importance (Kanner et al. 1991). An increase in the amount of NHI as a result of thermal processes on meat systems has been demonstrated by several authors (Schricker et al. 1982, Lombardi-Boccia et al. 2002). Gomez-Basauri and Regenstein (1992a, 1992b), suggested cooking is not as important as the subsequent refrigerated storage of cooked meats for the release of NHI from Mb.

The relationship between oxidative processes and the release of iron from Mb and the effect of these chemical changes on color characteristics of cooked products is still not well understood.

The increase of NHI could have some important consequences, affecting both the nutritional and technological properties of liver pate. The degradation of heme iron would reduce the nutritional value of the pates in terms of bioavailability of iron, since HI is more available than NHI (Hunt and Roughead 2000). Furthermore, iron achieves enhanced ability for promoting oxidation processes when it is released from the heme molecule (Kanner et al. 1991), and therefore, pates with increasing amounts of NHI might also have increased oxidative susceptibility.

From a nutritional point of view, Ahn and Kim (1998) reported that the status of ionic iron is more important than the amount of iron.

Traditionally, researchers have determined the discoloration of meat using as criterion the brown color of the product, calculated as percent of MMb (Mancini et al. 2003). These authors demonstrated that in the estimation of the shelf life of beef or veal (considered as discoloration of the product), the diminution in the percent of OMb is a better tool than the increase in percent of MMb.

Occasionally, when the meat cut contains bone (especially in pork and beef), the haemopigments (mainly Hb) present in the medulla lose color because the erythrocytes are broken during cutting and accumulate on the surface of the bone Hb. When exposed to light and air, the color of the Hb changes from bright red (OHb) characteristic of blood to brown (MHb) and even black (Gill 1996). This discoloration basically takes place during long periods of storage and especially during shelf life display (Mancini et al. 2004). This characteristic is aggravated if the product is kept in a modified atmosphere rich in oxygen (Lanari et al. 1995). These authors also point out that the effect of bone marrow discoloration is minimized by the effect of bacterial growth in modified atmosphere packaging.

As in the case of fresh meat, the shelf life of meat products is limited by discoloration (Mancini et al. 2004). This phenomenon is important in this type of product because they are normally displayed in illuminated cabinets. Consequently, the possibility of nitrosated pigments photo-oxidation of (NOMb) needs to be taken into account. During this process, the molecule is activated because it absorbs light; this may subsequently deactivate the NOMb and give the free electrons to the oxygen to generate MMb and free nitrite.

In model systems of NOMb photo-oxidation, this effect can be diminished by adding solutions of dextrose, which is a very important component of the salts used for curing cooked products and in meat emulsions.

When a meat product is exposed to light or is stored in darkness, the use of ascorbic acid or its salts may help stabilize the product's color. Such behavior has been described both in model systems of NOMb (Walsh and Rose 1956) and in dry-cured meat products (e.g., "longanizas" and Spanish dry-fermented sausage). However, when sodium isoascorbate or erythorbate is used in "longaniza" production, color stability is much reduced during the retail process (Ruíz-Peluffo et al. 1994).

The discoloration of white meats like turkey is characterized by a color changes, which go from pink/yellow to yellow/brown, while in veal/beef the changes go from purple to grayish/brown. In turkey, it has been demonstrated that the presence or absence of lipid oxidation depends on, among other things, the concentration of vitamin E in the tissues. The color and lipid oxidation are interrelated, since it has been seen that lipid oxidation in red and white muscle depends on the predominant form of catalyzing iron, Mb, or free iron (Mercier et al. 1998).

Compared with red meat, tuna flesh tends to undergo more rapid discoloration during refrigerated storage. Discoloration due to oxidation of Mb in red fish presented a problem, even at low temperature. This low color stability might be related to the lower activity or poorer stability of MMb reductase in tuna flesh (Ching et al. 2000). One of the reasons of this behavior is that aldehydes known to be produced during lipid oxidation can accelerate tuna OMb oxidation in vitro (Lee et al. 2003). Also, tuna flesh could be immersed in MMb reductase solution that could extend the color stability of tuna fish. Also, the use

of this enzyme can reduce metMb formation during refrigerated storage of tuna (Tze et al. 2001).

Yellowtail (*Seriola quinqueradiata*) fillets stored in gas barrier film packs filled with N_2 and placed in cold storage at 0–5°C, stayed fresh for 4–7 days. N_2 or CO_2 packaging did not prevent discoloration in frozen tuna fillets; better results were achieved by thawing the frozen tuna meat in an O_2 atmosphere (Oka 1989). Packaging in atmospheres containing 4% or 9% O_2 was inferior to packaging in air, as they promoted MMb formation. Packaging in 70% O_2 maintained the fresh red color of tuna dorsal muscle for storage periods less than 3 days (Tanaka et al. 1996). In order to change the dark brown color into a bright red color, processors sometimes treat with 100% carbon monoxide (CO) during modified atmosphere packaging. This may result in high CO residues in the flesh and may cause health problems, since Mb can react with CO rapidly even at low CO concentration (Chi et al. 2001).

MICROORGANISMS AND COLOR

Although the real limiting factor in the shelf life of fresh meat is the microbial load, the consumer chooses it according to its color. The bacterial load is usually the most important cause of discoloration in fresh meat and meat products (sausages and other cooked products), so slaughter, cutting, and packaging must be strictly controlled.

Bacterial contamination decisively affects the biochemical mechanisms responsible for the deterioration of meat (Renerre 1990). An important aspect to take into account is that, just as with the bacterial load, the effect is more pronounced in meats that are more strongly pigmented (beef) than in less pigmented meats like pork and chicken (Gobantes and Oliver 2000).

Another variable affecting color stability in meat is the quantity of microorganisms present (Houben et al. 1998), a concentration in excess of 10^6 per gram having a strong effect. Although antioxidants, such as ascorbic acid, slow down lipid oxidation and consequently improves color stability, they (antioxidants) do not alter color changes caused by bacterial growth (Zerby et al. 1999).

Biochemistry of Fermented Meat

Fidel Toldrá

Abstract: A wide variety of fermented sausages are produced, the type and composition depending on the raw materials, microbial population, and processing conditions. Undry and semidry sausages are fermented to reach low pH values, and are usually smoked and cooked before consumption. Dry-fermented sausages experience a long drying after fermentation reaching low water activity values. This chapter describes the raw ingredients including microbial starters used for the manufacture of fermented sausages as well as its main processing stages. The physical and chemical changes that take place during processing are also described.

BACKGROUND INFORMATION

The origin of fermented meats is quite far away in time. Ancient Romans and Greeks already manufactured fermented sausages, and, in fact, the origin of words like sausage and salami might have come from the Latin expressions *salsiccia* and *salumen*, respectively (Toldrá 2002). The production and consumption of fermented meats expanded throughout Europe in the Middle Ages, being adapted to climatic conditions (i.e., smoked in Northern Europe and dried in Mediterranean countries). The experience in manufacturing these meats went to America with settlers (e.g., states like Wisconsin still have a good number of typical Northern European sausages like Norwegian and German sausages).

Today, a wide variety of fermented sausages are produced, depending on the raw materials, microbial population, and processing conditions (Toldrá et al. 2007). For instance, Northern European-type sausages contain beef and pork as raw meats, are ripened for short periods (up to 3 weeks), and are usually subjected to smoking. In these sausages, shelf-life is mainly due to acid pH and smoking rather than drying. On the other hand, Mediterranean sausages mostly use only pork and are ripened for longer periods (several weeks or even months), and smoke is not so typically applied (Flores and Toldrá 1993). Examples for different types of fermented sausages, according to the intensity of drying, are shown in Table 18.1. Undry and semidry sausages are fermented to reach low pH values, and are usually smoked and cooked before consumption. Shelf-life and safety is mostly determined by pH drop and reduced water activity (a_w) as a consequence of fermentation and drying, respectively. The product may be considered stable at room temperature when pH < 5.0 and the moisture:protein ratio is below 3.1:1 (Sebranek 2004). Moisture:protein ratios are defined for the different dry and semidry fermented sausages in the Unites States, while a_w values are preferred in Europe.

Table 18.1. Examples of Fermented Meats with Different Dryness Degrees

Product	Type	Examples	Weight Loss (%)	Drying/Ripening
Undry fermented sausages	Spreadable	German teewurst	<10	No drying
		Frische mettwurst	<10	No drying
Semidry fermented sausages	Sliceable	Summer sausage	<20	Short
		Lebanon bologna	<20	Short
		Saucisson dáAlsace	<20	Short
		Chinese Laap cháeung	<20	Short
		Chinese Xunchang	<20	Short
Dry fermented sausages	Sliceable	Hungarian and Italian salami	>30	Long
		Pepperoni	>30	Long
		Spanish chorizo	>30	Long
		Spanish salchichón	>30	Long
		French Saucisson	>30	Long

RAW MATERIAL PREPARATION

There are several considerations (listed in Table 18.2) that need to be taken into account when producing fermented meats. The selection of the different options, which are discussed in the later sections, facilitates the choice of the most adequate conditions for the correct processing, safety, and optimal final quality.

INGREDIENTS

Lean meats from pork and beef, in equal amounts, or only pork are generally used. Quality characteristics such as color, pH (preferably < 5.8), and water-holding capacity are very important. When the pH of pork meat is >6.0, the meat is known as DFD (dark, firm, and dry). This type of meat binds water tightly and spoils easily. Pork meat with another defect, known as PSE (pale, soft, and exudative), is not recommended because the color is pale, and the sausage would release water too fast, which could cause casings to wrinkle. Meat from older animals is preferred because of its more intense color, which is due to the accumulation of myoglobin, a sarcoplasmic protein that is the natural pigment responsible for color in meat (Toldrá and Reig 2007).

Pork back and belly fats constitute the main source for fats. Special care must be taken for the polyunsaturated fatty acid

Table 18.2. Some Decisions to Adopt and Options to Choose in the Processing of Fermented Meats

Aspects	Options
Type of meat	Pork, beef, etc.
Quality of meat	Choose good quality. Reject defective meats (pork PSE and DFD), abnormal colors, exudation, etc.
Origin of fat	Choose either chilled, or frozen (how long?) fats. Reject oxidized fats.
Type of fat	Control of fatty acids profile (excess of PUFA?).
Ratio	Choose desired meat:fat ratio.
Particle size	Choose adequate plate (grinder) or speeds (cutter).
Additives: Salt	Decide concentration.
Additives: Curing agent	Nitrite or nitrate depending on type and length of process.
Additives: Carbohydrates	Type and concentration depending on type of process and required pH drop.
Spices	Choose according to required specific flavor.
Microflora	Natural or added as starter?
Starters	Choose microorganisms depending on type of process and product.
Casing	Material and diameter depending on type of product.
Fermentation	Conditions depending on type of starter used and product.
Ripening/drying	Conditions depending on type of product.
Smoking	Optional application. Conditions depending on type of product and specific flavor.
Color	Depends on raw meat, nitrite and processing conditions.
Texture	Depends on meat:fat ratio, stuffing pressure and extent of drying.
Flavor	Choose adequate starter and process conditions.
Water activity	Depends on drying conditions and length of process.

PSE, pale, soft, and exudative; DFD, dark, firm, and dry; PUFA, polyunsaturated fatty acids.

profile, which should be lower than 12%; and the level of oxidation, measured as peroxide value, should be as low as possible (Demeyer 1992). Some rancidity may develop after long-term frozen storage since lipases present in adipose tissue are active even at temperatures as low as $-18°C$ and are responsible for the continuous release of free fatty acids that are susceptible to oxidation (Hernández et al. 1999). So, extreme caution must be taken with fats stored for several months as they may develop a rancid flavor.

OTHER INGREDIENTS AND ADDITIVES

Salt is the oldest additive used in cured meat products since ancient times. Salt, at about 2–4%, serves several functions, including (1) an initial reduction in a_w, (2) providing a characteristic salty taste, and (3) contributing to increased solubility of myofibrillar proteins. Nitrite is a typical curing agent used as a preservative against pathogens, especially *Clostridium botulinum*. Nitrite is also responsible for the development of the typical cured meat color, prevention of oxidation, and contribution to the cured meat flavor (Gray and Pearson 1984). The reduction of nitrite to nitric oxide is favored by the presence of ascorbic and erythorbic acids or their sodium salts. They also exert antioxidative action and inhibit the formation of nitrosamines.

Carbohydrates like glucose and lactose are used quite often as substrates for microbial growth and development. Disaccharides, and especially polysaccharides, may delay the growth and pH drop rate because they have to be hydrolyzed to monosaccharides by microorganisms.

Sometimes, additional substances may be used for specific purposes (Demeyer and Toldrá 2004). This is the case of glucono-delta-lactone, added at 0.5%, which may simulate bacterial acidulation. In the presence of water, glucono-delta-lactone is hydrolyzed to gluconic acid and produces a rapid decrease in pH. The quality is rather poor because the rapid pH drop drastically reduces the activity of flavor-related enzymes such as exopeptidases and lipases. Phosphates may be added to improve stability against oxidation; vegetable proteins, such as soy isolates, to replace meat proteins; and manganese sulfate as a cofactor for lactic acid bacteria.

Spices, either in natural form or as extracts, are added to give a characteristic aroma or color to the fermented sausage. There are a wide variety of spices (pepper, paprika, oregano, rosemary, garlic, onion, etc.), each one giving a particular aroma to the product. Some spices also contain powerful antioxidants. The most important aromatic volatile compounds may vary depending on the geographical and/or plant origin. For instance, garlic, which gives a pungent and penetrating smell, is typically used in chorizo, and pepper is used in salchichón and salami. Paprika gives a characteristic flavor and color due to its high content of carotenoids (Ordoñez et al. 1999). The presence of manganese in some spices, like red pepper and mustard, is necessary for the activity of several enzymes involved in glycolysis and thus enhances the generation of lactic acid (Lücke 1985).

STARTERS

Typical fermented products were initially based on the development and growth of desirable indigenous flora, sometimes reinforced with backslopping, which consists in the addition of a previous ripened, fermented sausage with adequate sensory properties. However, this practice usually gave a high heterogeneity in the product quality. The microbiota in spontaneously fermented sausages have been identified in many different types of sausages worldwide. The most frequent microorganisms found were *L. curvatus, Lb. plantarum, Lb. sakei, St. carnosus, St. xylosus,* and *St. saprophyticus* (Paramithitis et al. 2010).

The use of microbial starters, as a way to standardize processing as well as quality and safety, is relatively new. In fact, the first commercial use was in the United States in the 1950s, followed by its use in Europe in the 1960s; since then, starters have seen extensive use. Today, most of the fermented sausages are produced with a combination of lactic acid bacteria, to get an adequate acidulation, and two or more cultures to develop flavor and facilitate other reactions, such as nitrate reduction.

In general, microorganisms used as starter cultures must satisfy several requirements according to the purposes of their use: nontoxicity for humans, good stability under the processing conditions (resistance to acid pH, low a_w, tolerance to salt, resistance to phage infections), intense growth at the fermentation temperature (i.e., 18–25°C in Europe or 35–40°C in the United States), generation of products with technological interest (i.e., lactic acid for pH drop, volatile compounds for aroma, nitrate reduction, secretion of bacteriocins, etc.), and lack of undesirable enzymes (e.g., decarboxylases responsible for amine generation). Thus, the most adequate strains must be carefully selected and controlled as they will have a very important role in the process and will be decisive for the final quality. The most important microorganisms used as starters belong to one of the following groups: lactic acid bacteria, coagulase-negative staphylococci, Micrococcaceae, yeasts, or molds (Leistner 1992). These microorganisms provide a good number of enzymes involved in relevant biochemical changes like the enzymatic breakdown of carbohydrates, proteins, and lipids that affect color, flavor, and texture (Flores and Toldrá 2010). It must be taken into account that these enzymes will be affected by the temperature of fermentation and ripening, a_w and pH decrease during the process, the length of ripening time, the content of salt, nitrate and nitrite, the type and content of carbohydrates, and the presence of spices (Stahnke and Tjener 2007). The main roles and functions for each group are shown in Table 18.3.

LACTIC ACID BACTERIA

The most important function of lactic acid bacteria consists in the generation of lactic acid from glucose or other carbohydrates through either homo- or heterofermentative pathway. The accumulation of lactic acid produces a pH drop in the sausage. However, some undesirable secondary products, like acetic acid, hydrogen peroxide, acetoin, etc., may be generated in case of certain species having heterofermentative pathways. *L. sakei* and *L. curvatus* grow at mild temperatures and are usual in

Table 18.3. Main Roles and Effects of Microorganisms in Fermented Meats

Group	Microorganisms	Primary Role	Secondary Role	Chemical Contribution	Effects
Lactic acid bacteria	*L. sakei, L. curvatus, L. plantarum, L. pentosus, P. acidilactici, P. pentosaceus*	Glycolysis	Proteolysis (endo and exo)	Lactic acid generation Generation of free amino acids	pH drop Safety Firmness Taste
Micrococcaceae	*K. varians, S. Xylosus, S. carnosus*	Nitrate reductase, lipolysis, Catalase	Proteolysis (exo)	Reduction of nitrate to nitrite Generation of free fatty acids, ready to oxidation Generation of free amino acids Degradation of hydrogen peroxide	Safety Aroma Taste
Yeasts	*Debaryomyces hansenii*	Lipolysis	Deamination/ deamidation Transamination	Generation of free fatty acids Transformation of amino acids Lactic acid consumption and generation of ammonia	Aroma Taste pH rise
Molds	*Penicillium nalgiovense, P. chrysogenum*	Lipolysis, proteolysis (exo)	Deamination/ deamidation Transamination	Generation of free fatty acids, ready to oxidation Generation of free amino acids and its transformation Generation of ammonia	Aroma Taste pH rise external aspect

the processing of European sausages while *L. plantarum* and *P. acidilactici* grow well at higher temperatures (30–35°C) closer to the fermentation conditions in the sausages produced in the United States. Lactic acid bacteria also have a proteolytic system, consisting in endo- and exopeptidases, that contributes to the generation of free amino acids during processing and most of them are also able to generate different types of bacteriocins with antimicrobial properties. Recently, an absence of effect of certain lactic acid bacteria like *L. curvatus*, *L. sakei*, *Str. Griseu*, and *P. pentosaceus* was reported in American dry sausages ripened for a short time and finally heat processed (Candogan et al. 2009).

MICROCOCCACEAE

This group consists of *Staphylococcus* and *Kocuria* (formerly *Micrococcus*), which are major contributors to flavor due to their proteolytic and lipolytic activities (Casaburi et al. 2006). However, *L. curvatus* and *S. xylosus* were reported to have no significant effect on proteolysis and lipolysis (Casaburi et al. 2007), although the sensory characteristics were observed to improve in long-ripened sausages (Casaburi et al. 2008). Another important function consists of the nitrate reductase activity, necessary to reduce nitrate to nitrite and contribute to color formation and safety. However, these microorganisms must be added in high amounts because they grow little or even die just at the onset of fermentation, when low pH conditions prevail. Preferably, low pH-tolerant strains should be carefully selected. The species from this family also have an important catalase activity that contributes to color stability and, somehow, prevention of lipid oxidation.

YEASTS

Debaryomyces hansenii is the predominant yeast in fermented meats, mainly growing in the outer area of the sausage due to its aerobic metabolism. *D. hansenii* has a good lipolytic activity and is able to degrade lactic acid. In addition, it also exhibits an important deaminase/deamidase activity, using free amino acids as substrates and producing ammonia as a subproduct that raises the pH in the sausage (Durá et al. 2002). *D. hansenii* has also some proteases of interest like proteases A, B, and D, as well as prolyl and arginyl aminopeptidases (Bolumar et al. 2005, 2006a, 2008).

MOLDS

Some typical Mediterranean dry fermented sausages have molds on the surface. The most usual are *Penicillium nalgiovense* and *P. chrysogenum*. They contribute to flavor through their proteolytic and lipolytic activity, and to appearance in the form of a white coating on the surface (Sunesen and Stahnke 2003). They also generate ammonia through their deaminase and deamidase activities and contribute to pH rise. Inoculation of sausages with natural molds present in the fermentation room is dangerous because toxigenic molds might grow. So, fungal starter cultures are mainly used as a preventive measure against the growth of other mycotoxin-producing molds and give a typical white color on the surface as demanded in certain Mediterranean areas.

CASINGS

Casings may be natural, semisynthetic, or synthetic, but a common required characteristic is its permeability to water and air.

Natural casings are natural portions of the gastrointestinal tract of pigs, sheep, and cattle, and although irregular in shape, they have good elasticity, tensile strength, and permeability. Natural casings are typically used for traditional sausages because they give a homemade aspect to the product. Semisynthetic casings are based on collagen that shrinks with the product and is permeable, but cannot be overstuffed (Toldrá et al. 2002). Synthetic cellulose-based casings are nonedible but are preferred for industrial processes due to important advantages such as controlled and regular pore size, uniformity for standard products, and hygiene. These casings are easily peeled off.

A wide range of sizes, between 2 and 15 cm, may be used, depending on the type of product. Of course, the diameter strongly affects fermentation and drying conditions. So, pH drop is more important in large-diameter sausages, where drying is more difficult to achieve.

PROCESSING STAGE 1: COMMINUTION

An example of a flow diagram for the processing of fermented sausages is shown in Figure 18.1. Chilled meats, pork alone or mixtures of pork and beef, and porcine fats are submitted to comminution in a grinder (Fig. 18.2). There are several plates with different hole sizes depending on the desired particle size. Previous trimming for removal of connective tissue is recommended, especially when processing undry or semidry fermented sausages where no further hydrolysis of collagen will oc-

Figure 18.2. Grinding of meats and fats. There are many sizes of grinder plates in accordance to the required particle size.

cur. Salt, nitrate and/or nitrite, carbohydrates, microbial starters, spices, sodium ascorbate, and optionally, other nonmeat proteins are added to the ground mass, and the whole mix is homogenized under vacuum to avoid bubbles and undesirable oxidations that affect color and flavor (Fig. 18.3). Grinding and mixing take several minutes, depending on the amount. Industrial processes may use a cutter, as an alternative to grinding and mixing, when the required particles sizes are small. The cutter consists in a slowly moving bowl, containing the meats, fat, and additives, which rotates against a set of knives operating with rapid rotation. The fat and meat must be prefrozen ($-6°C$ to $-7°C$) to avoid smearing of fat particles during chopping. This phenomenon consists in a fine film of fat formed over the lean parts that may reduce the release of water during drying (Roca and Incze 1990). The cutter operates under vacuum to avoid any damage by oxygen,

although the operation takes only a short time, just a few minutes, and the ratio of bowl speed to knife speed determines the desired particle size.

PROCESSING STAGE 2: STUFFING

The mixture is stuffed under vacuum into casings—natural, collagen-based, or synthetic—with both extremes clipped. The vacuum avoids the presence of bubbles within the sausage and disruptions in the casing. The stuffing must be adequate in order to avoid smearing of the batter, and temperature must be kept below 2°C to avoid this problem. Once stuffed (Fig. 18.4), the sausages are hung in racks and placed in natural or air-conditioned drying chambers.

PROCESSING STAGE 3: FERMENTATION

FERMENTATION TECHNOLOGY

Once sausages are stuffed, they are placed in computer-controlled air-conditioned chambers and left to ferment for microbial growth and development. A typical chamber is shown in Figure 18.5. Temperature, relative humidity, and air speed must be carefully controlled in order to have correct microbial growth and enzyme action. The whole process can be considered as a lactic acid solid-state fermentation in which several simultaneous processes take place: (1) microbial growth and development, (2) biochemical changes, mainly enzymatic breakdown of carbohydrates, proteins, and lipids, and (3) physical changes, mainly acid gelation of meat proteins and drying.

Meat fermentation technology differs between the United States and Europe. High fermentation temperatures (35–40°C) are typical in US sausages, followed by a mild heating process, as a kind of pasteurization, instead of drying, to kill any *Trichinella*. Thus, starters such as *Lactobacillus plantarum* or *Pediococcus*

acidilactici, which grow well at those temperatures, are typically used. In Europe, different technologies may be found, depending on the location and climate. There is a historical trend toward short-processed, smoked sausages in cold and humid countries, as in Northern Europe, and long-processed, dried sausages in warmer and drier countries, as in the Mediterranean area. In the case of Northern European countries, sausages are fermented for about 3 days at intermediate temperatures (25–30°C), followed by short ripening periods (up to 3 weeks). These sausages are subjected to a rapid pH drop and are usually smoked for a specific flavor (Demeyer and Stahnke 2002). On the other hand, Mediterranean sausages require longer processing times. Fermentation takes place at milder temperatures (18–24°C) for about 4 days, followed by mild drying conditions for a longer time, usually several weeks or months. *L. sakei* or *L. curvatus* are the lactic acid bacteria most often used as starter cultures (Toldrá et al. 2001). The time required for the fermentation stage is a function of the temperature and the type of microorganisms used as starters.

The technology is quite different in China and other Asian countries. Sausages are first dried over charcoal at 48°C and 65% relative humidity for 36 hours and then at 20°C and 75% relative humidity for 3 days. Water activity rapidly drops below 0.80, although pH remains at about 5.9, which is a relatively high value. Fermentation is relatively poor, and the sour taste, which is considered undesirable, is reduced. Chinese raw sausage is consumed after heating (Leistner 1992).

MICROBIAL METABOLISM OF CARBOHYDRATES

The added carbohydrate is converted, during the fermentation, into lactic acid of either the D($-$) or L($+$) configuration, or a mixture of both, depending on the species of lactic acid bacteria used

as starter. The ratio between the L- and D-enantiomers depends on the action of L- and D-lactate dehydrogenase, respectively, and the presence of lactate racemase. The rate of generation and the final amount of lactic acid depend on the type of lactic acid bacteria species used as starter, the type and content of carbohydrates, the fermentation temperature, and other processing parameters. The accumulation of lactic acid produces a pH drop, more or less, intense depending on its generation rate. Some secondary products such as acetic acid, acetoin, and others may be formed through heterofermentative pathways (Demeyer and Stahnke 2002). Acid pH favors protein coagulation, as it approaches its isoelectric point, and thus also favors water release. Acid pH also contributes to safety by contributing to the inhibition of undesirable pathogenic or spoilage bacteria. The pH drop favors initial proteolysis and lipolysis by stimulating the activity of muscle cathepsin D and lysosomal acid lipase, both active at acid pH, but an excessive pH drop does not favor later enzymatic reactions involved in the generation of flavor compounds (Toldrá and Verplaetse 1995).

PROCESSING STAGE 4: RIPENING AND DRYING

Temperature, relative humidity, and air flow have to be carefully controlled during fermentation and ripening to allow correct microbial growth and enzyme action while maintaining adequate drying progress. The air velocity is kept at around 0.1 m/s, which is enough for a good homogenization of the environment. Ripening and drying are important for enzymatic reactions related to flavor development and obtaining the required water loss and thus reduction in a_w. The length of the ripening/drying period takes from 7 to 90 days, depending on many factors, including the kind of product, its diameter, dryness degree, fat content, desired flavor intensity, and so on. The reduction in a_w is slower in beef-containing sausages. The casing must remain attached to the sausage when it shrinks during drying. In general, long-ripened products tend to be drier and more flavorful.

PHYSICAL CHANGES

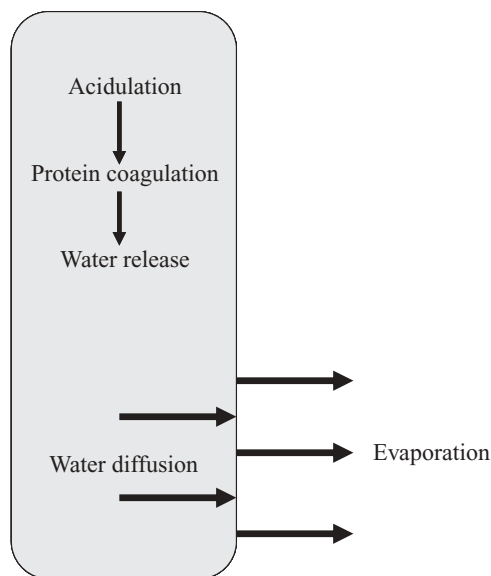
The most important physical changes during fermentation and ripening/drying are summarized in Figure 18.6. The acidulation produced during the fermentation stage induces protein coagulation and thus some water release. The acidulation also reduces the solubility of sarcoplasmic and myofibrillar proteins, and the sausage starts to develop consistency. The drying process is a delicate operation that must achieve an equilibrium between two different mass transfer processes—diffusion and evaporation (Baldini et al. 2000). Water inside the sausage must diffuse to the outer surface and then evaporate to the environment. Both rates must be in equilibrium because a very fast reduction in the relative humidity of the chamber would cause excessive evaporation from the sausage surface that would reduce the water content on the outer parts of the sausage, causing hardening. This is typical of sausages of large diameter because of the slow water diffusion rate. The cross section of these sausages shows a darker, dry, hard outer ring. On the other hand, when the water


Figure 18.6. Scheme showing important physical changes during the processing of fermented meats.

diffusion rate is much higher than the evaporation rate, water accumulates on the surface of the sausage, causing a wrinkled casing. This situation may happen in small-diameter sausages being ripened in a chamber with high relative humidity. The progress in drying reduces the water content, up to 20% weight loss in semidry sausages and 30% in dry sausages (Table 18.1). The a_w decreases according to the drying rate, reaching values below 0.90 for long-ripened sausages.

CHEMICAL CHANGES

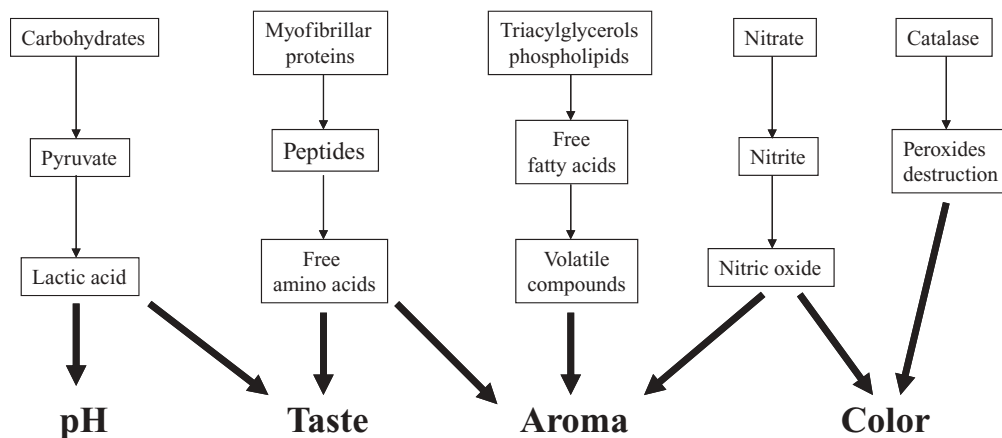
There are different enzymes, of both muscle and microbial origin, involved in reactions related to color, texture, and flavor generation. These reactions, which are summarized in Figure 18.7, are very important for the final sensory quality of the product. One of the most important groups of reactions, mainly affecting myofibrillar proteins and yielding small peptides and free amino acids as final products, is known as proteolysis (Toldrá 1998). An intense proteolysis during fermentation and ripening is mainly carried out by endogenous cathepsin D, an acid muscle proteinase that is very active at acid pH. This enzyme hydrolyses myosin and actin, producing an accumulation of polypeptides that are further hydrolyzed to small peptides by muscle and microbial peptidyl peptidases and to free amino acids by muscle and microbial aminopeptidases (Sanz et al. 2002). The generation of small peptides and free amino acids increases with the length of processing, although the generation rate is reduced at acid pH values because the conditions are far from optimal for enzyme activity. Free amino acids may be further transformed into other products, for example, volatile compounds through Strecker degradations and Maillard reactions; ammonia through


Figure 18.7. Scheme showing the most important reactions by muscle and microbial enzymes involved in chemical and biochemical changes affecting sensory quality of fermented meats.

deamination and/or deamidation reactions by deaminases and deamidases, respectively, present in yeasts and molds; or amines by microbial decarboxylases.

Another important group of enzymatic reactions, affecting muscle and adipose tissue lipids, is known as lipolysis (Toldrá 1998). Thus, a large amount of free fatty acids (between 0.5% and 7%) is generated through the enzymatic hydrolysis of triacylglycerols and phospholipids. Most of the observed lipolysis is attributed, after extensive studies on model sterile systems and sausages with added antibiotics, to endogenous lipases present in muscle and adipose tissue (e.g., lysosomal acid lipase, present in the lysosomes and very active at acid pH; Toldrá 1992, Hierro et al. 1997, Molly et al. 1997).

Catalases are mainly present in microorganisms such as *Kocuria* and *Staphylococcus;* they are responsible for peroxide reduction and thus contribute to color and flavor stabilization. Nitrate reductase, also present in these microorganisms, is also important for reducing nitrate to nitrite in slow-ripened sausages with an initial addition of nitrate. Recently, two strains of *Lactobacillus fermentum* have proved to be able to generate nitric oxide and give an acceptable color in sausages without nitrate/nitrite. This could be used to produce cured meats free of nitrate and nitrite (Moller et al. 2003).

PROCESSING STAGE 5: SMOKING

Smoking is mostly applied in Northern countries with cold and/or humid climates. Initially, it was used for preservation purposes, but today its contribution to flavor and color is more important (Ellis 2001). In some cases, smoking can be applied just after fermentation or even at the start of the fermentation. Smoking can be accompanied by heating at 60°C and has a strong impact on the final sensory properties. It has a strong antioxidative effect and gives a characteristic color and flavor to the product, which is the primary role of smoking. The antimicrobial effect of some smoking compounds, especially phenols,

carboxylic acids, and formaldehyde inhibit the growth of certain bacteria even though some yeasts and molds may be resistant (Sikorski and Kolakowski 2010).

SAFETY

The stability of the sausage against pathogen and/or spoilage microorganisms is the result of successive hurdles (Leistner 1992). Initially, the added nitrite curing salt is very important for the microbial stability of the mix. During mixing under vacuum, oxygen is gradually removed, and redox potential is reduced. This effect is enhanced when ascorbic acid or ascorbate is added. Low redox potential values inhibit aerobic bacteria and make nitrite more effective as bactericide. During the fermentation, lactic acid bacteria can inhibit other bacteria, not only by the generation of lactic acid (and the subsequent pH drop), but also by generation of other metabolic products such as acetic acid and hydrogen peroxide and, especially, bacteriocins (low-molecular mass peptides synthetized in bacteriocin-positive strains; Lücke 1992). The drying of the sausage continues the reduction in a_w to low values (a_w below 0.92) that inhibit growth of spoilage and/or pathogenic microorganisms. Thus, the correct interaction of all these factors assures the stability of the product.

Some foodborne pathogens that might be found in fermented meats are briefly described. *Salmonella* is more usual in fresh, spreadable sausages (Lücke 1985), but can be inhibited by acidification to pH 5.0 and/or drying to $a_w < 0.95$ (Talon et al. 2002). Lactic acid bacteria exert an antagonistic effect against *Salmonella* (Roca and Incze 1990). *Staphylococcus aureus* may grow under aerobic or anaerobic conditions and requires $a_w < 0.91$ for inhibition, but is sensitive to acid pH. So, it is important to control the elapsed time before reaching the pH drop in order to avoid toxin production. Furthermore, this toxin is produced only in aerobic conditions (Roca and Incze 1990). *Clostridium botulinum* and its toxin-producing capability are affected by a rapid pH drop and low a_w even more than by the addition of

Table 18.4. Safety Aspects: Generation of Undesirable Compounds in Dry Fermented Meats.

Compounds	Route of Formation	Origin	Concentrations (mg/100g)
Tyramine	Microbial decarboxylation	Tyrosine	<16.0
Tryptamine	Microbial decarboxylation	Trytophan	<6.0
Phenylethylamine	Microbial decarboxylation	Phenylalanine	<3.5
Cadaverine	Microbial decarboxylation	Lysine	<0.6
Histamine	Microbial decarboxylation	histidine	<3.6
Putrescine	Microbial decarboxylation	Ornithine	<10.0
Spermine	Microbial decarboxylation	Methionine	<3.0
Spermidine	Microbial decarboxylation	Methionine	<0.5
Cholesterol oxides	Oxidation	Cholesterol	<0.15

lactic acid bacteria and nitrite (Lücke 1985). *Listeria monocytogenes* is limited in growth at $a_w < 0.90$ combined with low pH values and specific starter cultures (Hugas et al. 2002). *Escherichia coli* is rather resistant to low pH and a_w but is reduced when exposed to $a_w < 0.91$ (Nissen and Holck 1998). Adequate prevention measures consist in correct cooling and a hazard analysis critical control point (HACCP) plan with application of good manufacturing practices (GMP), sanitation, and strict hygiene control of personnel and raw materials.

In recent years, most attention has been paid to biopreservation as a way to enhance preservation against spoilage bacteria and foodborne pathogens. The bioprotective culture consists in a competitive bacterial strain that grows very fast or produces antagonistic substances like bacteriocins. Another precise way consists in the direct addition of purified bacteriocins. Those bacteriocins belonging to group IIa (also called pediocin-like) that display inhibition against *Listeria* have been reported to be the most interesting for the meat industry (Hugas et al. 2002).

Parasites like *Trichinella spiralis* are almost eliminated through modern breeding systems. Pork meat free of trichinae must be used as raw material for fermented sausages; otherwise, heat treatments of the sausage to reach internal temperatures above 62.2°C are required to inactivate them (Sebranek 2004).

The generation of undesirable compounds, listed in Table 18.4, depends on several factors. The most important factor is the hygienic quality of the raw materials. For instance, the presence of cadaverine and/or putrescine may be indicative of the presence of contaminating meat flora. Another factor is processing conditions, which may favor the generation of biogenic amines; however, the type of natural flora or microbial starters used for the process is the most important issue, because the presence of microorganisms with decarboxylase activity can induce the generation of biogenic amines. In general, tyramine is the amine generated in higher amounts, and it is formed by certain lactic acid bacteria that exhibit enzymatic activity for decarboxylation of tyrosine (Eerola et al. 1996). Tyramine releases noradrenaline from the sympathetic nervous system, and the peripheral vasoconstriction and increase in cardiac output result in higher blood pressure and risk for hypertensive crisis (Shalaby 1996). However, the estimated tolerance level for tyramine (100–800 mg/kg) is higher than for other amines (Nout

1994). The amines derived from foods are generally degraded in humans by the enzyme monoamine oxidase (MAO) through oxidative deamination reactions. Those consumers using MAO inhibitors are less protected against amines and are thus susceptible for risk situations such as hypertensive crisis when ingesting significant amounts of amines. Other amines may also cause problems; for example, phenylethylamine, which may cause migraine and an increase in blood pressure; or histamine, which excites the smooth muscles of the uterus, the intestine, and the respiratory tract. Biogenic amines may be typically found in traditional fermented meat products (Roseiro et al. 2010). One way to reduce health risks from amines consists in the use of starter cultures that are unable to produce amines but are competitive against amine-producing microorganisms. Additionally, the use of microorganisms that exhibit amine oxidase activity and are able to degrade amines, the selection of raw materials of high quality, and the use of GMP assures products of high quality and reduced risks (Talon et al. 2002). Finally, the generation of nitrosamines during the process is almost negligible due to the restricted amount of nitrate and/or nitrite that can be initially added and the low amount of residual nitrite remaining by the end of the process (Cassens 1997, Honikel 2010).

The processing conditions may favor the oxidation of cholesterol. Some generated oxides can be involved in cardiovascular-related diseases (e.g., 7-ketocholesterol and α-5,6-epoxycholesterol), but in general, the reported levels of all cholesterol oxides is very low, less than 0.15 mg/100 g, for exerting any toxic effect (Demeyer et al. 2000).

FINISHED PRODUCT

Once the product is finished, it is packaged and distributed. Fermented sausages can be sold as either entire or as thin slices (Fig. 18.8). The developed color, texture, and flavor depend on the processing and type of product. Main sensory properties are described in the forthcoming sections.

COLOR

The color of the sausage depends on the moisture and fat content as well as its content of hemoprotein, particularly myoglobin.
Figure 18.8. Picture of a typical small-diameter salchichón, showing its cross section.

Color is also influenced by pH drop rate and the ultimate pH, but it may be also affected by the presence of spices like red pepper. An excess of acid generation by lactobacilli may also affect color.

The characteristic color is due to the action of nitrite with myoglobin. Nitrite is reduced to nitric oxide, favored by the presence of ascorbate/erythorbate. Myoglobin and nitric oxide may then interact to form nitric oxide myoglobin, which gives the characteristics cured pinkish-red color (Pegg and Shahidi 1996). This reaction is favored at low pH. Long-processing sausages using nitrate need some time for the growth of Micrococcaceae before pH drops. Nitrate reductase, which is present in Micrococcaceae, reduces nitrate to nitrite, which is afterwards further reduced to nitric oxide, which can react with myoglobin. Oxidative discoloration consists in the conversion of nitrosylmyoglobin to nitrate and metmyoglobin, which affects the oxidative stability because of the pro-oxidant effect of ferric heme.

TEXTURE

The consistency of fermented meats is initiated with the salt addition and pH reduction. The water-binding capacity of myofibrillar proteins decreases as pH approaches its isoelectric point and releases water. The solubility of myofibrillar proteins is also reduced, with a trend toward aggregation and coagulation, forming a gel. The consistency of this gel increases with water loss during drying. So, there is a continuous development of textural characteristics such as firmness, hardness, and cohesiveness of meat particles during drying (Toldrá 2002). The meat:fat ratio

Table 18.5. Quality Aspects: Generation or Presence of Desirable Nonvolatile Compounds Contributing to Taste in Fermented Meats

Group of Compounds	Main Representative Compounds	Routes of Generation	Presence in Final Product	Main Contribution	Expected Intensity
Peptides	Tri and dipeptides	Proteolysis	Increases with length of process	Taste	High
Free amino acids	Glutamic acid, aspartic acid, alanine, lysine, threonine	Proteolysis	Increases with length of process	Taste	High
Nucleotides and nucleosides	Inosine monophosphate, guanosine monophosphate, inosine, hypoxanthine	ATP degradation	Around 100 mg/100 g	Taste enhancement	Low
Long chain free fatty acids	Oleic acid, linoleic acid, linolenic acid, arachidonic acid, palmitic acid	Lipolysis	Increases with length of process	Taste	Low
Short chain fatty acids	Acetic acid, propionic acid	Microbial metabolism	Depends on microflora	Taste	Medium
Acids	Lactic acid	Glycolysis	Depends on initial amount of sugar and fermentation	Sour taste	High
Carbohydrates	Glucose, lactose	Remaining (nonconsumed through glycolysis)	Depends on initial amount of sugar and microflora	Sweet taste	Low
Inorganic compounds	Salt	Addition	Depends on initial amount	Salty taste	High

may affect some of these textural characteristics, but, in general, the final texture of the sausage will mainly depend on the extent of drying (Toldrá et al. 2004).

FLAVOR

Little or no flavor is usually detected before meat fermentation, although a large number of flavor precursors are present. As fermentation and further ripening/drying progress, the combined effect of endogenous muscle enzyme and microbial activity produces a high number of nonvolatile and volatile compounds with sensory impact. The longer the process, the more the accumulation of these compounds is increased and their sensory impact enhanced. Although not so important as in meat cooking, some compounds with sensory impact may be produced through further chemical reactions. The addition of spices also has an intense contribution to specific flavors.

TASTE

The main nonvolatile compounds contributing to taste of fermented meats are summarized in Table 18.5. Sour taste, mainly resulting from lactic acid generation through microbial glycolysis, is the most relevant taste in fermented meats. Sourness is also correlated with other microbial metabolites such as acetic acid.

Ammonia may be generated through deaminase and deamidase activities, usually present in yeasts and molds, reducing the intensity of the acid taste. Salty taste is usually perceived as a direct taste from salt addition. ATP (adenosine triphosphate)-derived compounds such as inosine monophosphate and guanosine monophosphate exert some taste enhancement, while hypoxanthine contributes to bitterness. Other taste contributors are those compounds resulting from protein hydrolysis. The generation and accumulation of small peptides and free amino acids contribute to taste perception, which increases with the length of process. Some of these small peptides (e.g., leucine, isoleucine, and valine) also act as aroma precursors, as described in Section "Aroma".

AROMA

The origin of aroma mainly depends on the ingredients and processing conditions. Different pathways are responsible for the formation of volatile compounds with aroma impact (Table 18.6). As mentioned previously, proteolysis gives rise to a large amount of small peptides and free amino acids. Microorganisms can convert the amino acids leucine, isoleucine, valine, phenylalanine, and methionine to important sensory compounds with low threshold values. Some of the most important are branched aldehydes such as 2- and 3-methylbutanal and 2-methylpropanal,

Table 18.6. Quality Aspects: Generation of Desirable Volatile Compounds Contributing to Aroma in Fermented Meats.

Group of Compounds	Main Representative Compounds	Routes of Generation	Main Aroma	Expected Contribution
Aliphatic aldehydes	Hexanal, pentanal, octanal, etc.	Oxidation of unsaturated fatty acids	Green	High
Strecker aldehydes	2- and 3-methylbutanal, etc.	Strecker degradation of free amino acids	Roasted cocoa, cheesy-green	High
Branched-chain acids	2- and 3-methyl butanoic acid	Secondary products of previous Strecker degradation	Sweaty	Medium
Alcohols	Ethanol, butanol, etc.	Oxidative decomposition of lipids	Sweet, alcohol, etc.	Low
Ketones	2-pentanone, 2-heptanone, 2-octanone, etc.	Lipid oxidation	Ethereal, soapy	Medium
Sulfides	Dimethyldisulfide	Strecker degradation of sulfur-containing amino acids (methionine)	Dirty socks	Low
Esters	Ethyl acetate, ethyl 2-methyl-butanoate	Interaction of carboxylic acids and alcohols	Pineapple, fruity	High
Hydrocarbons	Pentane, heptane, etc.	Lipids autoxidation	Alkane	Very low
Dicarbonyl products	Diacetyl, acetoin, acetaldehyde	Pyruvate microbial metabolism	Butter	Low
Nitrogen compounds	Ammonia	Deamination, deamidation	Ammonia	Variable, depends on growth of yeasts and molds

Source: Adapted from Viallon et al. (1996), Flores et al. (1997), Stahnke (2002), Toldrá (2002) and Talon et al. (2002).

branched alcohols such as 2- and 3-methylbutanol, acids such as 2- and 3-methylbutanoic and 2-methylpropanoic acids, and esters such as ethyl 2- and 3-methylbutanoate (Stahnke 2002). Some of these branched-chain aldehydes may also be formed through the Strecker degradation, consisting in the reaction of amino acids with diketones. However, conditions found in sausages are far from those optimal for this kind of reaction, which needs high temperature and low a_w (Talon et al. 2002).

Methyl ketones may be formed either by β-oxidation of free fatty acids or decarboxylation of free β-keto acids. Other non-branched aliphatic compounds generated by lipid oxidation are alkanes, alkenes, aldehydes, alcohols, and several furanic cycles.

A large number of volatile compounds are generated by chemical oxidation of the unsaturated fatty acids. These volatile compounds are mainly generated during ripening and further storage. Other low-molecular weight volatile compounds are generated by microorganisms from carbohydrate catabolism. The most usual compounds are diacetyl, acetoin, butanediol, acetaldehyde, ethanol, and acetic propionic and butyric acids. However, some of these compounds may be derived from pyruvate originated through other metabolic pathways than carbohydrate glycolysis (Demeyer and Stahnke 2002, Demeyer and Toldrá 2004). A comparison of the generation of certain volatile compounds between fat tissue and intramuscular fat in lean meat showed that major development took place in the intramuscular fat (Olivares et al. 2009). The flavor profile may have important variations depending on the type of microorganisms used as starters (Berdagué et al. 1993).

Biochemistry of Seafood Processing

Y. H. Hui, N. Cross, H. G. Kristinsson, M. H. Lim, W. K. Nip, L. F. Siow, and P. S. Stanfield

Abstract: Seafood is valued for its nutritive components and desirable sensory attributes. However, quality of seafood is vulnerable to rapid degradation if no appropriate postharvest handling or processing methods are used. It is important to understand the basic biochemical reactions of the relevant components in seafood in order that their quality can be best preserved. Biochemical changes in glycogen, protein, lipids, and pigments are discussed in detail and how such changes could affect the quality of seafood. Metabolic changes from the activity of enzymes can be used as indices of freshness and be monitored by biochemical or chemical methods. Three different manufacturing process techniques, (1) freezing, (2) dehydration, and (3) thermal are discussed with respect to the biochemical changes.

Yerlikaya P, Gokoglu N. 2010. Inhibition effects of green tea and grape seed extracts on lipid oxidation in bonito fillets during frozen storage. *Int J Food Sci Technol* 45(2): 252–257.

INTRODUCTION

Most of us like to eat seafood, especially when it is fresh, although processed products are also favorites of many consumers. In addition to sensory attributes, the preference for seafood now

includes awareness of its health benefits. Thus, when processing seafood, it is important to understand the scientific and technical reasons that are responsible for the sensory and health attributes of seafood, in addition to how the manufacturing process can affect the basic quality of seafood. The same knowledge may lead to a reduction in the perishability of seafood, a problem that has existed since the beginning of time, though it has been partially solved by many modern techniques including canning, freezing, and dehydration.

The nutritive value of seafood is well known for its content of protein and some minerals and, recently, its fat quality. For the past 20 years, considerable attention has been paid to the content of polyunsaturated omega-3 fatty acids in fish, especially their prevalence in fatty fish. Of course, one must not forget the relatively high levels of cholesterol in some fish and shellfish, especially crustaceans and squid. The biochemical changes in macronutrients of seafood are of interest to nutritionists, food processors, and consumers. Their importance in public health cannot be overestimated if one considers how seafood contributes to the nutrition and health of the human body. A short discussion of the nutritive values of fish serves as an introduction.

Perishability of seafood is important economically as well as for its safety. The price of seafood can drop drastically if it is not handled properly and is handled without refrigeration or other forms of preservation. The biochemical aspects of seafood will be discussed in this chapter using the following approaches:

- *Glycogen in seafood*: Biochemical changes in its glycogen, which exists in small quantities, initiates the biochemical process, in the same way that it occurs in other animal products.
- *Nitrogenous compounds in seafood*: The degradation of protein will be discussed, with a special reference to sarcoplasmic, myofibrillar, and stromal protein. This discussion is accompanied by a brief mention of nonprotein nitrogenous substances. Such biochemical changes in seafood's protein and nonprotein components usually reduce its economic value and may also create safety problems.
- *Lipids in seafood*: Fat can undergo many biochemical changes, both qualitatively and quantitatively. Some changes can cause rancidity, especially during the storage of fatty fish.
- *Pigments in seafood*: Biochemical changes will be discussed with reference to epithelial discoloration, hemoglobin, hemocyanin, myoglobin, carotenoids, and melanosis.
- *Quality indices in seafood*: The monitoring of the quality of seafood has been the subject of intense scientific research. Currently, the techniques available are lactic acid formation with lowering of pH, nucleotide catabolism, degradation of myofibrillar proteins, collagen degradation, dimethylamine (DMA) formation, free fatty acid (FFA) accumulation, and tyrosine accumulation.
- *Processing methods for seafood*: In the last 30 years, great advances have taken place in the processing of seafood.

The basic observation is simple. No matter what method is used or invented to process the products, their biochemistry is affected. Three types of processing techniques will be discussed in this chapter: freezing, drying, and heating.

When studying this chapter, the reader should refer to Chapter 1 of this book for more details on food biochemistry.

NUTRITIVE COMPOSITION OF THE MAJOR GROUPS OF SEAFOOD AND THEIR HEALTH ATTRIBUTES

As mentioned earlier, seafood is nutritious. It contains nutrients, some of which are essential to human health. The nutrients are divided into two groups: macronutrients and micronutrients. This first section covers the macronutrients (water, protein, lipids) and their changes during processing and preservation. This is followed by a discussion of the micronutrients (vitamins and minerals). The implications of undesirable metals in seafood are then discussed. Issues related to health attributes in seafood are presented last.

COMPOSITION

Macronutrients

The macronutrients found in seafood include protein, fats and oils, and water. All other nutrients found in seafood are considered micronutrients and are of minor significance. Fish contains 63–84% water, 14–24% protein, and 0.5–17% lipid by weight. Fish, like other muscle sources of protein, have only small amounts of carbohydrates (as muscle glycogen). The amount of protein is similar in pelagic and demersal fish. However, pelagic fish, commonly called fatty fish, are higher in lipids (9–17 g/100 g) than demersal fish that live at the bottom of the ocean (0.3–1.6 g/100 g).

The primary source of fish protein is muscle, and the protein quality is comparable to other animal protein from milk, eggs, and beef. Muscle from fish and shellfish has very little connective tissue and is readily hydrolyzed upon heating, resulting in a product that is tender and easy to chew.

The forms of lipid in fish are triglycerides or triacylglycerols. Triglycerides in pelagic fish contain the long-chain polyunsaturated fatty acids (PUFAs) 20:5v3 eicosapentoic acidand 22:6v3 docosahexanoic acid (DHA), which have many health benefits including normal development of the brain and retina in infants and prevention of heart diseases in adults.

Pelagic fish store lipids in the head and muscle, whereas lipids in demersal fish are stored primarily in the liver and peritoneal lining and under the skin, except in halibut, which has both liver and muscle stores. The lipid content of pelagic fish varies with the season, feeding ground, water salinity, and spawning. Fish do not feed during spawning but depend on lipid stores for energy. For example, the lipid content of salmon may be 13% when the salmon begins traveling upstream to spawning grounds in the spring and only 5% at the end of the spawning season in the fall. Herring show more seasonal variation in lipid content, with a peak level of 20% in the spring, which drops to 10–15% during

Table 19.1. Distribution of Water, Protein, and Lipids in 100 g of Raw Edible Fish including Bones and Cartilage

Fish	Water (g)	Protein (g)	Lipid (g)
Cod	79–81	17–19	0.6–0.8
Herring	78–80	18–20	0.5–0.7
Ling	79–80	17–19	0.6–0.8
Mackerel	63–65	17–19	15–17
Monkfish	82–84	14–16	0.3–0.5
Pilchard/sardine	66–68	19–21	8–10
Plaice	78–80	15–17	1.3–1.5
Saithe/coley	79–81	17–19	0.9–1.1
Salmon	66–68	19–21	10–12
Skate	79–81	14–16	0.3–0.5
Sole	80–82	16–18	1.4–1.6
Sprat	68–70	16–18	9–10
Trout (rainbow)	75–77	18–20	5–6
Tuna	69–71	22–24	4–5
Whiting	79–81	17–19	0.5–0.8

Table 19.2. Distribution of Water, Protein, and Lipid in 100 g of Cooked, Edible Fish

Fish	Water (g)	Protein (g)	Lipid (g)
Haddock (smoked)	71–72	23—24	0.8–1.0
Haddock (steamed)	78–79	20—21	0.5–0.7
Herring (grilled)	63–64	20—21	11–12
Mackerel (smoked)	47–48	18—20	30–31
Mackerel (grilled)	58–59	20—21	17–18
Salmon (smoked)	64–65	25—26	4–5
Salmon (steamed)	64–65	21—22	11–12
Salmon (breaded nuggets)	60–61	12—13	11–12
Tuna (canned in water)	75–76	25—26	0.9–0.9
Tuna (canned in oil)	64–65	26—27	0.8–0.9
Tuna (raw, fresh, or frozen)	70–71	23—24	4–5

the fall spawning season, and to 3–4% in the winter, because of colder water temperatures and a scarcity of food. Water replaces the lipid depleted from muscle tissue and results in fish of poor eating quality.

Livers of species of the Gadidae (cod) family contain 50% lipids and are a concentrated source of vitamins A and D and omega-3 fatty acids. Oil is commercially extracted from the liver and purified for medicinal use and animal feed. Livers from other species of fish (haddock, coley, ling, shark, huss, halibut, and tuna) are also commercially processed to extract the fish oil.

In general, processing does not change the nutrient content of fish. Drying and smoking fish reduces the water content. The process can also reduce the lipid content of the fish if extremely high temperatures are used. Drying also increases the concentration of all nutrients on a weight basis. Sodium nitrite (usually with sodium nitrate) that is added during the process of drying or smoking increases the content of sodium considerably. The salmon flesh used for smoking is lower in lipids than whole salmon.

Breading fish adds carbohydrate and yields a final product with a relatively lower concentrations of protein, vitamins, and minerals than unbreaded fish.

Freezing and canning do not change the nutrient composition of fish except for canned tuna. Most canned tuna is low in lipids, since the lighter colored tuna is lower in fat and is preferred by consumers over the deep brown-red-colored tuna. Tuna is also cooked prior to canning, which removes some of the lipid.

Tables 19.1 and 19.2 compare the water, protein, and lipid contents of different forms of fish.

The macronutrients in crustaceans and mollusks differ from those in bony fish, since all mollusks contain carbohydrate and lobster and scallops contain small amounts of carbohydrate. Carbohydrate in shellfish is in the form of glycogen. The protein content is more variable than in bony fish, and the lipid content is comparable to that in pelagic fish (see Table 19.3; refer to Tables 19.4 and 19.5 for comparison of micronutrients). Ranges

are used in Tables 19.1–19.5, because data from many sources are so variable.

Micronutrients

Micronutrients cover vitamins and minerals. Seafood is an important dietary source of vitamins A and D and the B vitamins B_6 and B_{12}. Although seafood is not high in thiamin or riboflavin, the amounts are comparable to those found in beef. Fish and shellfish have little or no vitamin C or folate.

Cod liver oil has been used to supplement diets with vitamins A and D; one teaspoon (5 g) of cod liver oil provides 12.5 µg of vitamin D and 1500 µg of vitamin A.

Mineral contributions of fish and shellfish include iodine and selenium; a 100 g portion contains more than 50% of the dietary reference intake (DRI) for iodine (DRI 5-150 µg/day) and selenium (DRI 5-55 µg/day), respectively. Generally, meat, eggs, and dairy products are poor sources of iodine and selenium. Iron and zinc are found in moderate amounts in most seafood. Clams and oysters are concentrated sources of zinc, with 24 and 91 mg/100 g serving, respectively, compared with a DRI of 15 mg/day. Seafood, similar to other dietary protein sources, is also an excellent source of potassium. Fresh seafood contains varying amounts of sodium, from a low of 31 mg/100 g of trout to a high of 856 mg/100 g of crab. Sodium is also added during canning and smoking fish and other seafood. In general, seafood is a poor source of calcium, except for whole canned salmon and sardines: when their bones are included, they will provide 200–400 mg calcium/100 g portion.

Other Components

Seafood, like other animal products, contains cholesterol. The cholesterol content in fish and mollusks ranges from 40 to 100 mg/100 g portion and is lower than in other meat such as beef, pork, and chicken. However, the shellfish, shrimp, and prawns are quite high in cholesterol—195 mg /100 g portion

Table 19.3. Distribution of Water, Protein, and Lipid in 100 g of Raw or Cooked Nonfish Seafood

Edible Nonfish Seafood	Water (g)	Protein (g)	Lipid (g)	Carbohydrate (g)
Crustacean varieties				
Crab (steamed)	77–78	19–20	1.5–1.6	0

Whelk (steamed)	32–33	47–48	0.8–0.9	15–16

of shrimp. The cholesterol content of shrimp is of interest to individuals with cardiovascular disease who are advised to limit dietary cholesterol to 300–400 mg/day. However, diets high in total fat and saturated fat also increase the risk for cardiovascular disease, and both shrimp and prawns contain negligible amounts of fat.

HEALTH ATTRIBUTES

In the history of mankind, fish has been considered to have special health attributes, especially in various ethnic populations. Recently, scientific research has confirmed certain claims and raised controversy in relation to others. Seafood is a rich source of omega-3 fatty acids and may be good for the heart. Fish is being recommended for people of all ages to prevent a variety of disorders. Fish is also being promoted for women during pregnancy, for children at risk for asthma, and in the elderly to reduce the risk of Alzheimer's disease. However, pregnant women and children have been advised to limit fish to prevent the risk of mercury toxicity. Natural habitats are becoming polluted with mercury that is taken up and stored in some varieties of fish. Fish farming is a rapidly growing enterprise and has the benefit of controlling the food and water supply to avoid possible contamination of fish with toxic materials.

Fish and shellfish are an important part of a healthy diet. Fish and shellfish contain high-quality protein and other essential

nutrients, are low in saturated fat, and contain two omega-3 fatty acids, eicosapentoic acid and DHA. The American Heart Association recommends that healthy adults eat at least two servings of fish a week (12 oz), especially varieties that are high in omega-3 fatty acids, such as mackerel, lake trout, herring, sardines, albacore tuna, and salmon.

Fish oil can help reduce deaths from heart disease, according to evidence in reports from the Agency for Healthcare Research and Quality (AHRQ, www.ahrq.gov/clinic/epcindex. htm#dietsup). A systematic review of the available literature found evidence that long-chain omega-3 fatty acids, the beneficial component ingested by eating fish or taking a fish oil supplement, reduce not only the risk for a heart attack and other problems related to heart and blood vessel disease in persons who already have these conditions, but also their overall risk of death. Although omega-3 fatty acids do not alter total cholesterol, HDL cholesterol, or LDL cholesterol, evidence suggests that they can reduce levels of triglycerides—a fat in the blood that may contribute to heart disease.

The AHRQ review reported evidence that fish oil can help lower high blood pressure slightly, may reduce the risk of coronary artery reblockage after angioplasty, may increase exercise capability among patients with clogged arteries, and may possibly reduce the risk of irregular heart beats—particularly in individuals with a recent heart attack. α-Linolenic acid (ALA), a type of omega-3 fatty acid from plants such as flaxseed, soybeans, and walnuts, may help reduce deaths from heart disease, but to a much lesser extent than fish oil.

On the basis of the evidence to date, it is not possible to conclude whether omega-3 fatty acids help improve respiratory outcomes in children and adults who have asthma. Omega-3 fatty acids appear to have mixed effects on people with inflam-

matory bowel disease, kidney disease, and osteoporosis, and no discernible effect on rheumatoid arthritis.

Depending on the stage of life, consumers need to be aware of both the benefits and risks of eating fish. Fish may contain mercury, which can harm an unborn baby or young child's developing nervous system. For most people, the risk from mercury by eating fish and shellfish is not a health concern. However, the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) are advising women who may become pregnant, pregnant women, nursing mothers, and young children to avoid some types of fish known to be high in mercury content.

The risks from mercury in fish and shellfish depend on the amount of fish and shellfish eaten and the levels of mercury in the fish and shellfish. Nearly all fish and shellfish contain traces of mercury, but two varieties of fish high in omega-3 fatty acids (mackerel and albacore tuna) may contain high amounts of mercury. Larger fish that have lived longer have the highest levels of mercury because they have had more time to accumulate it. These large fish (swordfish, shark, king mackerel, and tilefish) pose the greatest risk. Other types of fish and shellfish may be eaten in the amounts recommended by the FDA and EPA (www.FDA.gov).

By following these recommendations for selecting and eating fish or shellfish, women and young children will receive the benefits of eating fish and shellfish and be confident that they have reduced their exposure to the harmful effects of mercury:

- Avoid eating fish that contain high levels of mercury: shark, swordfish, king mackerel, or tilefish.
- Eat up to 12 oz (two average meals) a week of a variety of fish lower in mercury: shrimp, canned light tuna, salmon,

pollock, and catfish. However, limit intakes of albacore ("white") tuna to 6 oz (one average meal) per week because albacore has more mercury than canned light tuna.

- Check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas. Some kinds of fish and shellfish caught in local waters may have higher or much lower than average levels of mercury. This depends on the levels of mercury in the water in which the fish are caught. Those fish with much lower levels may be eaten more frequently and in larger amounts. If no advice is available, eat up to 6 oz (one average meal) per week of fish you catch from local waters, but do not consume any other fish during that week.

For young children, these same recommendations can be followed, except that a serving size for children is smaller than for adults, 2–3 oz for children instead of 6 oz.

BIOCHEMISTRY OF GLYCOGEN DEGRADATION

When the fish or crustacean animals are being caught, they struggle vigorously in the fishing gear and on board, causing antemortem exhaustion of energy reserves, mainly glycogen, and high-energy phosphates. Asphyxia phenomena set in with gradual formation of anoxial conditions in the muscle. Tissue enzymes continue to metabolize energy reserves. Degradation of high-energy phosphates eventually produces hypoxanthine, followed by formation of formaldehyde, ammonia, inorganic phosphate, and ribose phosphates. The degradation of glycogen in fish follows the Embden-Meyerhof-Parnas pathway via the amylolytic route, catalyzed by endogenous enzymes. This results in an accumulation of lactic acid and a reduction of pH (7.2 to 5.5), contracting the tissues and inducing rigor mortis (Hobbs 1982, Hultin 1992a, Sikorski et al. 1990a). The rate of glycolysis is temperature dependent and is slowed by a lower storage temperature.

BIOCHEMISTRY OF PROTEIN DEGRADATION

Approximately 11–27% of seafood (fish, crustaceans, and mollusks) consists of crude proteins. The types of seafood proteins, similar to other muscle foods, may be classified as sarcoplasmic, myofibrillar, and stromal. The sarcoplasmic proteins, mainly albumins, account for approximately 30% of the total muscle proteins. A large proportion of sarcoplasmic proteins are composed of hemoproteins. The myofibrillar proteins are myosin, actin, actomyosin, and troponin; these account for 40–60% of the total crude protein in fish. The rest of the muscle proteins, classified as stromal, consist mainly of collagenous material (Shahidi 1994).

SARCOPLASMIC PROTEINS

Sarcoplasmic proteins are soluble proteins in the muscle sarcoplasm. They include a large number of proteins such as myoglobin, enzymes, and other albumins. The enzymatic degrada-

tion of myoglobin is discussed in the section on pigment degradation. Sarcoplasmic enzymes are responsible for quality deterioration of fish after death and before bacterial spoilage. The significant enzyme groups are hydrolases, oxidoreductases, and transferases. Other sarcoplasmic proteins are the heme pigments, parvalbumins, and antifreeze proteins (Haard et al. 1994). Glycolytic deterioration in seafood was discussed in Chapter 1 of this book and will not be repeated here. Changes in the heme pigments will be covered in the Section on "Biochemical Changes in Pigments during Handling, Storage, and Processing". Hydrolytic deterioration of seafood myofibrillar and collagenous proteins are discussed in the Section on "Myofibrillar Protein Deterioration."

MYOFIBRILLAR PROTEIN DETERIORATION

The most common myofibrillar proteins in the muscles of aquatic animals are myosin, actin, tropomyosin, and troponins C, I, and T (Suzuki 1981). Myofibrillar proteins undergo changes during rigor mortis, resolution of rigor mortis, and long-term frozen storage. The integrity of the myofibrillar protein molecules and the texture of fish products are affected by these changes. These changes have been demonstrated in various research reports and reviews (Kye et al. 1988, Sikorski et al. 1990a, Martinez 1992, Haard 1992a, 1992b, 1994, Sikorski and Pan 1994, Sikorski 1994a, 1994b, Jiang 2000). The degradation of myofibrillar proteins in seafood causes these proteins to lose their integrity and gelation power in ice-stored seafood. The cooked seafood will no longer possess the characteristic firm texture of very fresh seafood; it will show a mushy or soft (sometimes mislabeled as tender) mouthfeel. For frozen seafoods, these degradations are accompanied by a loss in the functional characteristics of muscle proteins, mainly solubility, water retention, gelling ability, and lipid emulsifying properties. This situation gets even worse when the proteins are cross-linked due to the presence of formaldehyde formed from trimethylamine degradation. The cooked products become tough, chewy, and stringy or fibrous. Repeated freezing and thawing make the situation even worse. Readers should refer to the review by Sikorski and Kolakowska (1994) for a detailed discussion of the topic.

STROMAL PROTEIN DETERIORATION

The residue remaining after extraction of sarcoplasmic and myofibrillar proteins is known as stromal protein. It is composed of collagen and elastin from connective tissues (Sikorski and Borderias 1994). Degradation causes textural changes in these seafoods (honeycombing in skipjack tuna and mackerel and mushiness in freshwater prawn) (Frank et al. 1984, Nip et al. 1985, Pan et al. 1986). Bremner (1992) reviewed the role of collagen in fish flesh structure, postmortem aspects, and the implications for fish processing, using electron microscopic illustrations. Jiang (2000) reviewed the proteinases involved in the textural changes of postmortem muscle and surimi-based products. Microstructural changes in ice-stored freshwater prawns have been revealed (Nip and Moy 1988). These textural changes are due to the degradation of collagenous matter and definitely influence the quality of seafood. For

example, in freshwater prawn, the development of mushy texture downgrades its quality. In tuna, the development of honeycombing is an undesirable defect. In the postcooking examination of tuna before filling into the cans, the appearance of honeycombing is a sign of mishandling of the raw material. In more extensive cases, it may even cause the rejection of the precooked fish for further processing into canned tuna.

BIOCHEMICAL CHANGES IN NONPROTEIN NITROGENOUS COMPOUNDS

Reviews on the postmortem degradation of nonprotein nitrogenous (NPN) compounds are available (Sikorski et al. 1990a, Haard et al. 1994, Sikorski and Pan 1994). Such compounds in the meat of marine animals vary among species, with the habitat, and with life cycle; more importantly, they play a role in the postmortem handling processes (Sikorski et al. 1990a, Sikorski 1994a). Bykowski and Kolodziejski (1983) reported that white meat generally contains less NPN compounds than dark meat. For example, in the meat of white fish, the NPN generally made up 9–15% of the total nitrogen, in clupeids 16–18%, in muscles of mollusks and crustaceans 20–50%, and in some sharks up to 55%. Ikeda (1979) showed that about 95% of the total amount of NPN in the muscle of marine fish and shellfish is composed of free amino acids, imidazole dipeptides, trimethylamine oxide (TMAO) and its degradation products, urea, guanidine compounds, nucleotides and the products of their postmortem changes, and betaines.

The content of free amino acids in the body of oysters is higher in the winter than it is in the summer (Sakaguchi and Murata 1989).

The endogenous enzymatic breakdown of TMAO to DMA and then to formaldehyde and the bacterial reduction of TMAO to TMA have been most extensively studied. It should be noted that the production of DMA and formaldehyde takes place mainly in anaerobic conditions (Lundstrom et al. 1982).

Shark muscles contain fairly high amounts of urea, and ammonia may accumulate due to the activity of endogenous urease after death. This problem renders shark meat with ammonia odor unacceptable. Fortunately, this problem can be overcome by complete bleeding of the shark at the tail, gutting, filleting, and thorough washing right after catch to reduce the amount of substrate (urea). This procedure has been successfully practiced to provide acceptable shark meat for consumers.

After death, fish muscle also produces large amounts of ammonia due to degradation of adenosine triphosphate (ATP) to adenosine monophosphate (AMP), followed by deamination of AMP.

It should be noted that both ammonia production and degradation of TMAO can be either endogenous or contributed by bacteria. Ammonia, TMA, small amounts of DMA, and methylamine constitute the "total volatile base (TVB)," an indicator of freshness commonly used for seafood.

Postmortem enzymatic breakdown of nucleotides in fish may have a positive or negative impact on the flavor of seafood. The production of inosine monophosphate (IMP) at a cer-

tain concentrations in dried fish product can enhance the flavor (Murata and Sakaguchi 1989). Hypoxanthine contributes to bitterness and may add undesirable notes to the product (Lindsay 1991).

LIPIDS IN SEAFOODS

LIPID COMPOSITION

Lipids play an important nutritional role in seafoods, but at the same time, they contribute greatly to quality changes in many species. Just as aquatic species vary widely biologically, the lipid content and fatty acid types are greatly variable between species and sometimes within the same species. This can create a challenge for the seafood harvester and processor since varying amounts of lipids and the presence (or absence) of certain fatty acids can lead to significantly different effects on quality and shelf life. Seafood can be roughly classified into four categories based on fat content (O'Keefe 2000). Lean species (e.g., cod, halibut, pollock, snapper, shrimp, and scallops) have fat contents below 2%; low-fat species (e.g., yellowfin tuna, Atlantic sturgeon, and smelt) have fat contents between 2% and 4%; medium-fat species (e.g., catfish, mullet, trout, and salmon) are classified as having 4–8% total fat; and fatty species (e.g., herring, mackerel, eel, and sablefish) are classified as having more than 8% total fat. However, this classification is not valid for many species, since they can fluctuate widely in composition between seasons. For example, Atlantic mackerel can have less than 4% fat during late spring shortly after spawning, while it can have about 24% fat during late November due to active feeding (Leu et al. 1981; Fig. 19.1).

Different parts of the aquatic animal will also have different fat contents. Ohshima et al. (1993a) reported the following descending order for the fat content of mackerel and sardines:

- Skin (including subcutaneous lipids),
- Viscera,
- Dark muscle, and
- White muscle.

Some species, most notably salmonids, have larger fat deposits in the belly flaps than in other parts of the fish. Distribution of fat in many fish seems to be in descending fat levels from the head to the tail (Icekson et al. 1998, Kolstad et al. 2004). Diet will have a significant impact on the fat content and fatty acid profiles of aquatic animals. Aquacultured fish on a controlled diet, for example, do not show the same seasonal variation in fat content as wild species. It is also possible to modify the fat content and fat type via diet. For example, adding fish oil to fish feed will increase the fat content of fish (Lovell and Mohammed 1988), usually proportionately to the level of fat/oil in the diet (Solberg 2004). It has also been shown with many species (salmon being the most investigated) that the fatty acid composition is a reflection of the fatty acid composition in the fish diet (Jobling 2004). Therefore, it is possible to selectively increase the nutritional value of aquacultured fish by increasing the level and improving the ratio of nutritionally beneficial fatty acids (Lovell and Mohammed 1988). Conversely, one can
Figure 19.1. Seasonal variation in the fat content in different parts of Atlantic mackerel. (Adapted from Leu et al. 1981.)

decrease the level of unstable fatty acids to increase the shelf life of the product. A good example is catfish (Table 19.6), which in the wild has more unstable (but more nutritionally beneficial) fatty acids than grain-fed aquacultured catfish (Angelo 1996).

Table 19.6. Fatty Acid Composition of Extracted Lipids from Wild and Pond-Reared Channel Catfish

Fatty Acids	Wild (%)	Pond-Reared (%)

Source: Adapted from Chanmugam et al. (1986).

Although varying levels of total fat content in fish can influence quality, fatty acid type rather than quantity appears to be more important. The major classes of lipids in fish are triglycerides and phospholipids. Triglycerides, the majority of lipids in fish (except very lean fish), are neutral lipids. They exist as either large droplets within the adipose tissue or smaller droplets between or within muscle cells (Undeland 1997). These lipids are deposited and stored as an energy source for fish (Huss 1994). The phospholipids, which are polar lipids, are one of the main building blocks of muscle cell membranes and are usually present only at low levels, 0.5–1.1% (O'Keefe 2000). Some muscles of very lean species such as cod, pollock, and whiting can contain less than 1% lipids, most of which are in the form of membrane phospholipids.

Compared with other animals, aquatic animals are especially rich in long-chain PUFAs, which are found in higher numbers in the membrane phospholipids than in storage triglycerides (Hultin and Kelleher 2000). Aquatic animals adapted to cold water also have higher levels of PUFAs than those adapted to warmer waters, since more unsaturation is essential to maintain membrane fluidity and function at low temperatures. It has been reported that about half of the membrane phospholipids in cold-water fish are the omega-3 fatty acids eicosapentoic acid (20:5v3) and DHA (22:6v3) (Shewfelt 1981). These fatty acids have been found to be highly active physiologically, for example, leading to decreased plasma triacylglycerols, cholesterol, and blood pressure (Wijendran and Hayes 2004) and modulating immunological activities (e.g., inflammation) (Klurfeld 2002), to name a few important functions.

LIPIDS AND QUALITY PROBLEMS

Even though the phospholipids are at very low levels compared to neutral fats, they are believed to lead to more quality problems such as lipid oxidation, which is a major cause of quality

deterioration in many aquatic foods. This is in part because of their higher level of unsaturation, but also is due to their significantly larger surface area compared with neutral lipids (Hultin and Kelleher 2000). Undeland et al. (2002) tested this hypothesis in a model system with cod membrane lipids and varying levels of neutral menhaden lipids and hemoglobin as a prooxidant. The oxidation was found to be independent of the amount of neutral lipids in the system. Their larger surface area also makes the unstable phospholipids more exposed to a variety of prooxidants (and antioxidants) such as heme proteins, radicals, iron, and copper. These prooxidants are especially rich in the metabolically more active dark muscle, which is in turn more susceptible to lipid oxidation than white muscle. These prooxidants, especially the heme proteins hemoglobin and myoglobin, can lead to high levels of lipid oxidation products, especially as pH of the muscle is reduced (which occurs postmortem) or when muscle is minced and these components are mixed in with lipids and oxygen (Hultin 1994, Undeland et al. 2004). The secondary products formed as a result of lipid oxidation have highly unpleasant off-odors and flavors, and they can also adversely affect the texture and color of the muscle. Several studies have suggested a link between lipid oxidation and protein oxidation (e.g., Srinivasan et al. 1996, King and Li 1999, Tironi et al. 2002). Oxidation of proteins can lead to protein cross-linking and thus textural defects, including muscle toughening and loss of water-holding capacity. King and Li (1999) proposed that lipid oxidation products may also induce protein denaturation, which in turn could cause textural problems.

Although oxidation is often delayed during frozen storage of fish muscle, thawed fish can oxidize more rapidly than fresh fish since muscle cells are disrupted, leading to an increase in free iron and copper, among other changes (Hultin 1994, Benjakul and Bauer 2001). Much frozen seafood has also been found to accumulate high levels of FFAs over time as a result of lipase and phospholipase activity (Reddy et al. 1992, Undeland 1997). These FFAs may or may not be more susceptible to lipid oxidation (Shewfelt 1981), but they can lead to protein denaturation and cross-linking and thus adverse effects on texture and water-holding capacity (Reddy et al. 1992).

Conflicting results have been reported on the effect of thermal processing on lipids. Canning has been reported to increase oxidation (Aubourg 2001). Short-term heating to 80°C, in contrast to long-term heating, has been reported to reduce oxidation due to inactivation of lipoxygenases, while long-term heating may accelerate nonenzymatic oxidation reactions (Wang et al. 1991). Shahidi and Spurvey (1996) reported that cooked dark muscle of mackerel oxidized more than raw dark muscle, while interestingly, the opposite was found for white muscle. In a study where herring was cooked by various methods (microwave, boiling, grilling, and frying), there was essentially no effect on lipid oxidation (Regulska-Ilow and Ilow 2002). That same study also demonstrated that fish lipids, including the nutritionally important omega-3 fatty acids, were highly stable under the different cooking methods (Fig. 19.2). However, very high temperatures (e.g., 550°C) can lead to decomposition of fish fatty acids and thus to decreased nutritional value (Sathivel et al. 2003). Changes in seafood fatty acid profiles can occur with frying. It has been reported that there may be an exchange of fatty acids from the frying medium and the muscle (Sebedio et al. 1993). This can either lower or increase the nutritional quality and stability of the seafood, depending on the type of frying oil and the type of seafood.
Figure 19.2. Effect of different thermal treatments on fatty acids in herring. (Adapted from Regulska-Ilow and Ilow 2002.)
Figure 19.3. Effect of absence or presence of antioxidants (AO) on the oxidative stability of washed dark and white mackerel muscle during frozen storage (220°C). The antioxidant TBHQ was added during grinding, while ascorbate and EDTA were added during grinding and washing. (Adapted from Kelleher et al. 1992.)

Novel processing methods such as irradiation and high-pressure processing have been reported to lead to increased levels of lipid oxidation. High-pressure treatment has been reported to have relatively small effects on purified lipids from fish, while high-pressure treatment of fish muscle leads to high levels of lipid oxidation products (Ohshima et al. 1993a). This increase in oxidation is hypothesized, in part, to be via pressure-induced denaturation of heme proteins, which are potent prooxidants (Yagiz et al. unpublished data). Increased pressure and time also appears to lead to increased oxidation. Lipid hydrolysis has been found to be increased by medium levels of pressure, while it is reduced at high pressures, likely due to lipase inactivation (Ohshima et al. 1993b). Several studies have been conducted on the effect irradiation has on seafood quality, although this process is not allowed in many countries. It has been observed that low doses of gamma irradiation (5 kGy) may have an accelerating effect on the oxidative instability of some fish species and not others during postirradiation refrigerated storage. Al-Kahtani et al. (1996) reported that irradiation (1.5–10 kGy) led to more oxidation in tilapia and Spanish mackerel during refrigerated storage than in untreated fish. Fatty acid changes were also observed in that study. The likely cause for increased lipid oxidation on irradiation is the formation of radicals, more at higher levels of irradiation.

MINIMIZATION OF LIPID-DERIVED QUALITY PROBLEMS

To maintain or extend the sensory and nutritional qualities of seafood, it is important to minimize or delay the undesirable reactions of lipids, such as oxidation and hydrolysis. Time is of the essence with these reactions, and thus interventions should be done as early as possible to be able to extend quality as much as possible. The simplest means of controlling oxidation is maintaining low temperatures, since enzymatic and nonenzymatic oxidation reactions are greatly influenced by temperature (Hultin 1994). As mentioned before, very low temperatures such as freezing will accelerate lipid hydrolysis. However, hydrolysis as well as oxidation will be reduced if products are kept at extremely low frozen storage temperatures (e.g., below $-40°C$) compared with conventional frozen storage (about $-20°C$ or higher).

At the harvest level, bleeding fish can lead to significantly lower levels of oxidation, since heme proteins are reduced (Richards et al. 1998). Special care should be taken to prevent tissue disruption in storage, since both oxidation and hydrolysis will be increased. Washing fish fillets and fish mince will also remove significant amounts of heme proteins (Kelleher et al. 1992, Richards et al. 1998). Another effective way to reduce oxidation of unstable species is the removal of dark muscle, or deep skinning. This removes not only a large fraction of the heme proteins but also a large amount of oxidatively unstable lipids present in the dark muscle itself and below the skin. Protection from oxygen is another effective means for reducing oxidation. This can be achieved through modified atmosphere packaging, where oxygen is either reduced (for lean species) or completely removed (for fatty species). Vacuum packaging of seafood is also highly effective for reducing oxidation (Flick et al. 1992). Filleting fish under water (where O_2 is low) has also been reported to lead to less oxidation on storage than filleting in air (Richards et al. 1998). Special gases such as carbon monoxide have been found to significantly reduce oxidation of several species, even after fillets are removed from the gas, most likely since the gas reduces the prooxidative activities of heme proteins (Kristinsson et al. 2003).

Various antioxidative components can be highly effective in delaying lipid oxidation. All aquatic animals have a number of different indigenous antioxidants, and it is important to avoid conditions that can negatively affect or destroy these (Hultin 1994). It has been well researched and is well known that antioxidants can be added to seafood during processing to increase their oxidative stability (Fig. 19.3). Addition of antioxidants early during processing is also important. Since many of the prooxidants in seafood are in the aqueous phase and the lipids constitute a nonpolar phase, a combination of polar and nonpolar antioxidants has been found to be very effective. Tocopherol (vitamin E), a nonpolar antioxidant, and ascorbate (vitamin C), a polar antioxidant, are among the most commonly added antioxidants. Sometimes, metal chelators such as EDTA are added. However, it is worth mentioning that under certain conditions antioxidants can act as prooxidants. For example, this is true for ascorbic acid and EDTA, both of which can stimulate iron-mediated lipid oxidation. For example, when the ratio of EDTA: iron is 1, it is prooxidative, but when the ratio is .1, it is antioxidative (Halliwell and Gutteridge 1989). Since ascorbate is a reducing agent, it can also reduce iron under certain conditions and thus make it more prooxidative (Halliwell and Gutteridge 1988).

BIOCHEMICAL CHANGES IN PIGMENTS DURING HANDLING, STORAGE, AND PROCESSING

The main pigments in seafood can be classified as heme proteins (hemoglobin and myoglobin) in red-meat (warm-blooded) fish, hemocyanin in cold-blooded shellfish such as crustaceans and mollusks, and carotenoids in some important fish and shellfish products. The changes during handling, storage, and processing greatly affect the quality of these seafoods. Epithelial pigments and carotenoids also undergo changes during postmortem ice-chilled storage.

EPITHELIAL DISCOLORATION

The market value of squid is related to the contraction state of its epidermal chromatophores, called ommochromes. In recently harvested, prerigor squid, the pigment is dispersed throughout the chromatophores; hence, the dark red-brown appearance of the epithelial tissue. Following rigor mortis, the pigment cells contract, giving the skin a pale, light coloration dotted with dark flecks. The continued storage of squid results in a structural deterioration of the ommochrome membrane, leading to bleeding of pigment and downgrading of quality. The dark brown coloration characteristic of very fresh squid can be retained during processing, for example, by freezing or dehydration. However, improper storage of frozen or dried squid will result in chromatophore disruption and red discoloration of the meat (Hink and Stanley 1985).

The frozen storage of some fish may result in subcutaneous yellowing of flesh below the pigmented skin (Thompson and Thompson 1972). Apparently, freezing or other processes that disrupt chromatophores can lead to the release of carotenoids and their migration to the subcutaneous fat layer. Subcutaneous yellowing that occurs during the prolonged storage of frozen fish can originate from other causes, that is, yellowing associated with lipid oxidation and carbonyl-amine reactions.

HEMOGLOBIN

Normally, hemoglobin contributes less to the appearance of seafood than myoglobin because it is lost easily during handling and storage, while myoglobin is retained in the intracellular structure. The amount of hemoglobin present also affects to a greater extent the color appearance of light red and dark red muscles of red-meat fish flesh (Wang and Amiro 1979). For example, in yellowfin tuna *Neothunnus macropterus*, hemoglobin concentrations ranged from 12 to 50 mg% in light red muscle and 50 to 380 mg% in dark red muscle (Livingston and Brown 1981). The amount of residual hemoglobin in fish muscle is obviously influenced by the bleeding efficacy at the time of catch. Method of catch also affects the residual hemoglobin in the fish muscle. For example, the percent of total heme as hemoglobin in the meat of yellowfin caught by bait boat and purse seine was 24% and 32%, respectively (Barrett et al. 1965).

The green meat of raw or frozen broadbill swordfish (*Xiphias gladus*) is believed to be due to the combination of hemoglobin with hydrogen sulfide generated from the fairly extensive decomposition of the meat (Amano and Tomiya 1953).

Hemocyanin

Hemocyanin, not hemoglobin, is present in the blood of shellfish, that is, crustaceans and mollusks. Hemocyanins are copper-containing proteins, as compared with iron-containing proteins in hemoglobins, and they combine reversely with oxygen. The contribution of hemocyanins to seafood quality is not very well understood. It is suspected that the blue discoloration of canned crabmeat is associated with a high content of hemocyanin. The average copper content of blue meat (e.g., 2.8 mg%) is higher than meat of normal color (e.g., 0.5 mg%) (Ghiretti 1956).

Myoglobin

Myoglobin in fish muscle is retained in the intracellular structure. In fish muscle, the red, white, and intermediate fibers tend to be more distinctively segregated than they are in muscle from land animals. The myoglobin content in muscle of yellowfin tuna was found to range from 37 to 128 mg% in the light-colored muscle and from 530 to 22,400 mg% in the dark-colored muscle (Wolfe et al. 1978). In cod, the deep-seated, dark-colored muscle is richer in myoglobin than superficial dark-colored muscle (Brown 1962, Love et al. 1977).

Myoglobin in fish is easily oxidized to a brown-colored metmyoglobin. The discoloration of tuna during frozen storage is associated with the formation of metmyoglobin, depending on temperature and location (Tichivangana and Morrissey 1985).

Greening is a discoloration problem associated with cooking various tunas. The problem arises from the formation of a sulfhydryl adduct of myoglobin in the presence of an oxidizing

agent (e.g., TMAO). This greening problem can be effectively prevented by the use of a reducing agent (e.g., sodium hydrosulfite or another legally permitted additive) (Tomlinson 1966, Koizumi and Matsura 1967, Grosjean et al. 1969).

Carotenoids

The carotenoids contribute to the attractive yellow, orange, and red color of several important fish and shellfish products. The more expensive seafoods such as lobster, shrimp, salmon, and red snapper have orange-red integument and/or flesh from carotenoid pigments. For example, the red color of salmon is directly related to the price of the product. Carotenoids in seafoods may be easily oxidized by a lipogenase-like enzyme (Schwimmer 1981).

Melanosis (Melanin Formation)

Melanosis (melanin formation) or "blackspot" in shrimp during postmortem storage is caused by phenol oxidase and has economic implications (Simpson et al. 1987). Consumers consider shrimp with blackspot to be defective. This problem can be overcome by the use of appropriate reducing or inhibiting agent(s).

A comprehensive review of the biochemistry of color and color change in seafood was presented by Haard (1992a). Readers should refer to this reference for detailed information on this subject.

BIOCHEMICAL INDICES

Postharvest biochemical events in fish can be classified into two phases: metabolic (enzymatic) and microbial (Eskin et al. 1971). A discussion of microbial events is not the objective of this chapter. If interested, please consult references in this chapter or other sources. Abundant literature is available. Physical and instrumental methods for assessing seafood quality were reviewed by Sorenson (1992).

The metabolic (enzymatic) changes result from the activity of enzymes remaining in the fish flesh after death. Metabolites from these enzymatic changes can be used as indices of freshness and can be monitored by biochemical or chemical methods. The major metabolites coming from the actions of inherent enzymes in the fish themselves are lactic acid, nucleotide catabolites, collagen and myofibrillar protein degradation products, DMA formation, FFA accumulation, and tyrosine. Methodology for the analysis of these metabolites can be found in government publications such as Official Methods of Analysis of the American Association of Official Chemists in the United States.

Lactic Acid Formation with Lowering of pH

It is well known that, in animals, lactic acid accumulates during postmortem changes because of glycolytic conversion of storage glycogen in the muscle after cessation of respiration, and finfish, crustaceans, and shellfish are no exception. The metabolic pathway of glycogen degradation in animals was presented in Chapter 1 of this book. The accumulation of lactic acid can cause a drop in pH. Both lactic acid and pH can be measured without difficulty using modern instrumentation (Jacober and Rand 1982).

Nucleotide Catabolism

Postmortem dephosphorylation of nucleotides by autolysis in fish has been studied for many years as an index of quality. Nucleotide degradation commences with death and proceeds at a temperature-dependent rate (Spinelli et al. 1964, Eskin et al. 1971). Adenosine nucleotides are rapidly deaminated to IMP and further degraded from inosine to hypoxanthine during storage (Jones et al. 1964). There is no hypoxanthine in freshly caught fish and marine invertebrates. Accumulation of the metabolite hypoxanthine has attracted considerable attention for many years as an index of fish freshness. Hypoxanthine content can be determined by applying the colorimetric xanthine oxidase (EC 1.2.3.2) test. The rate of postmortem degradation of adenosine nucleotides in marine fish and invertebrates differs with the species and muscle type. For this reason, hypoxanthine analysis is of limited use for the evaluation of quality in certain species. It is most useful for the analysis of pelagics, redfish, salmon, and squid but is of little value for the estimation of lean fish quality (Gill 1992).

Because hypoxanthine is a metabolite fairly close to the end of the nucleotide degradation, Saito et al. (1959) proposed the use of K-value, defined as the ratio of inosine (HxR) plus hypoxanthine (Hx) to the total amount of ATP and related compounds (ADP, AMP, IMP, HxR, and Hx) in a fish muscle extract. Many researchers have demonstrated that K-value is related to fish freshness. However, its limitation is that it is difficult to analyze all these nucleotides and their metabolites by simple procedures. The use of high performance liquid chromatography offers accurate and reliable results but is not suitable for routine analysis. Since adenosine nucleotides rapidly break down and disappear within 24 hours postmortem, the K-value can be simplified as $(HxR + Hx)/(IMP + HxR + Hx)$. Karube et al. (1984) called it the K_1-value and reported that this value is strongly correlated to the K-value proposed by Saito et al. (1959). Like the K-value, the K_1-value is species dependent (Huynh et al. 1990).

Degradation of Myofibrillar Proteins

During chilled storage of fish and marine invertebrates, it is common to notice textural changes before bacterial spoilage. It is believed that these textural changes are caused by the autolytic degradation of myofibrillar proteins. This was demonstrated in ice-stored freshwater prawn (Kye et al. 1988) and in other finfish (Shewfelt 1980). Analysis of myofibrillar proteins is tedious and time-consuming using electrophoresis, but it will give a definite picture of protein degradation.

Collagen Degradation

In the tuna canning industry, it was long recognized that the appearance of honeycombing in precooked tuna was an index of

deterioration or mishandling. It was demonstrated that the appearance of honeycombing was related to collagen degradation (Frank et al. 1984). Mackerel was also shown to develop honeycombing when poorly handled (Pan et al. 1986). Freshwater prawn developed mushiness rapidly due to poor handling after catch. It was also demonstrated that this mushiness problem was related to collagen degradation (Nip et al. 1985). It should be noted that all these problems are observable only after the fish or prawn have been cooked and are only detected visibly. It is believed that these problems developed before bacterial spoilage of the fish. Analysis of collagen degradation is also tedious, involving hydrolysis of the extracted collagen and analysis of hydroxyproline.

DIMETHYLAMINE FORMATION

TMAO is commonly found in large quantities in marine species of fish, especially the elasmobranch (Jiang and Lee 2004) and gadoid (Bonnell 1994) species. After death, TMAO is readily degraded to DMA through a series of reactions during iced and frozen storage. DMA is typically observed in frozen gadoid species such as cod, hake, haddock, whiting, red hake, and pollock (Castell et al. 1973). TMAO degradation with DMA formation was enhanced by the presence of an endogenous enzyme (TMAOase) in the fish tissues, as observed in cod muscle by Amano and Yamada (1965). It should be noted that TMAO degradation can also be bacterial. Readers should consult the reviews by Regenstein et al. (1982), Hebard et al. (1982), Hultin (1992b), or other literature elsewhere.

FREE FATTY ACID ACCUMULATION

Postmortem lipid degradation in seafood, especially fatty fish, proceeds mainly due to enzymatic hydrolysis, with the accumulation of FFAs. About 20% of lipids are hydrolyzed during the shelf life of iced fish. The amount of FFAs is more or less doubled during that period, mostly from phospholipids, followed by triglycerides, cholesterol esters, and wax esters (Haard 1990, Sikorski et al. 1990b).

TYROSINE ACCUMULATION

The accumulation of lactic acid accompanied with a drop in pH causes the liberation and activation of inherent acid cell proteases, cathepsins (Eskin et al. 1971). Tyrosine has been reported to accumulate in stored fish due to autolysis. Its use as an index of freshness has been proposed by Shenouda et al. (1979) because of its simplicity in analysis. However, it was shown that the pattern of tyrosine accumulation was similar to that of the TVB, an indicator of bacterial spoilage. Therefore, its use as a biochemical index (before bacterial spoilage) is not sufficiently sensitive and specific enough to assess total fish quality (Simpson and Haard 1984).

BIOCHEMICAL AND PHYSICOCHEMICAL CHANGES IN SEAFOOD DURING FREEZING AND FROZEN STORAGE

Freezing is widely used to preserve and maintain the quality of food products for an extended period of time because microbial growth and enzymatic and biochemical reactions are reduced at low temperatures. However, ice crystals formed as a result of freezing may damage cells and disrupt the texture of food products, and the concentrated unfrozen matrix may result in changes in pH, osmotic pressure, and ionic strength. These changes can affect biochemical and physicochemical reactions such as protein denaturation, lipid oxidation, and enzymatic degradation of TMAO in frozen seafood. Therefore, it is essential to understand these reactions in order to extend the shelf life and improve the quality attributes of seafood.

PROTEIN DENATURATION

During freezing or frozen storage, changes in the physical state of water and the presence of lipids create an environment that induces protein denaturation. This denaturation can be caused by one or more of the following factors: (1) ice crystal formation, (2) dehydration effect, (3) increase in solute concentration, (4) interaction of protein with intact lipids and FFAs, and (5) interaction of protein with oxidized lipids (Shenouda 1980). Denaturation of protein changes the texture and functional properties of protein. The texture of fish may become more fibrous and tough as a result of the loss of protein solubility (Benjakul and Sutthipan 2009, Reza et al. 2009) and water-holding capacity. For example, the gel strength of rainbow fish (*Trichiurus savala*) protein significantly decreases after 100 days of storage at $-20°C$ (Mishra and Dora 2010). These textural changes as a result of protein changes give rise to undesirable sensory attributes, which are often described as sponginess, dryness, rubbery texture, and loss of juiciness (Haard 1992a). Tseng et al. (2003) suggested that to retain good eating qualities, that is, to maintain tenderness and cooking yield, and reduce lipid oxidation, red claw crayfish (*Cherax quadricarinatus*) should not be subjected to more than three freeze-thaw cycles.

ICE CRYSTAL EFFECT

Ice may form inter- and intracellularly during freezing, which ruptures membranes and changes the structure of the muscle cells (Mazur 1970, 1984, Friedler et al. 1988). At a slow freezing rate, fluids in the extracellular spaces freeze first, thus increasing the concentration of extracellular solutes and drawing water osmotically from the unfrozen cell through the semipermeable cellular membrane (Mazur 1970, 1984). The diffusion of water from the internal cellular spaces to the extracellular spaces results in drip, collected from frozen muscle tissues when thawed (Jiang and Lee 2004). Drip contains proteins, peptides, amino acids, lactic acid, purines, vitamin B complex, and various salts (Sulzbacher and Gaddis 1968), and their concentration in drip increases with storage time (Einen et al. 2002). On the other

hand, when the tissue is frozen rapidly, the cellular fluids do not have enough time to migrate out to the extracellular spaces and will freeze as small crystals uniformly distributed throughout the tissue (Mazur 1984). Thus, rapid freezing has a less detrimental effect on the cell or tissue (Coggins and Chamul 2004). However, if the storage temperature fluctuates, the intracellular ice recrystallizes, forming large ice crystals and causing cell disruption, which leads to drip loss as well. Mechanical damage from ice crystals on the texture of food during freezing and frozen storage has been studied in kiwi fruit (Fuster et al. 1994), lamb meat (Payne and Young 1995), squid mantle muscle (Ueng and Chow 1998), pork (Ngapo et al. 1999), and beef (Farouk et al. 2003).

During storage, if the product is not wrapped or is improperly packaged, ice may sublime into the headspace and produce a product defect called freezer burn (Blond and Le Meste 2004, Coggins and Chamul 2004). The sublimation of ice crystals leaves behind small cavities and causes the surface of fish to appear grayish. It is more pronounced when the storage temperature is high (Blond and Le Meste 2004). Freezer burn increases the rate of rancidity and discoloration because of the greater exposed surface, resulting in a "woody" (Blond and Le Meste 2004), tough, and dry texture in fish, making and leaving the fish less acceptable (Coggins and Chamul 2004).

Dehydration Effect

Native protein is stabilized by the folding of hydrophobic chains into the protein molecules and is held together by many other forces, including hydrogen bonding, dipole–dipole interactions, electrostatic interactions, and disulfite linkages (Benjakul and Bauer 2000). The formation of ice during freezing removes water from the protein molecules, thus disrupting the hydrogen bonding network between the native proteins and water molecules and exposing the hydrophobic or hydrophilic sites of the protein molecules (Shenouda 1980). The exposed hydrophobic or hydrophilic sites of the protein molecules interact with each other to form hydrophobic–hydrophobic and hydrophilic–hydrophilic bonds, either within the protein molecules, resulting in deconformation of the native three-dimensional structure of protein, or between adjacent protein molecules, causing protein–protein interactions and resulting in aggregation (Shenouda 1980). Xiong (1997) proposed that protein aggregates to maintain its lowest free energy as water forms ice, thus resulting in protein denaturation. Matsumoto (1979) suggested that redistribution of water during freezing allows protein molecules to move closer together and aggregate through intermolecular interactions. Lim and Haard (1984) found that the loss of protein solubility as a result of protein denaturation in Greenland halibut during frozen storage was mostly due to the noncovalent, hydrophobic interactions in protein molecules. Buttkus (1970) proposed that the formation of intermolecular S–S bonds is the major cause of protein denaturation.

Solute Concentration Effect

As ice forms, the concentration of mineral salts and soluble organic substances in the unfrozen matrix increases. As a result,

salts and other compounds that are only slightly soluble (such as phosphate) may precipitate out, which will change the pH (Einen et al. 2002) and ionic strength of the unfrozen matrix and cause conformational changes in proteins. Ions in the concentrated matrix will compete with the existing electrostatic bonds and cause the breakdown of some of the electrostatic bonds (Dyer and Dingle 1961, Shenouda 1980). Takahashi et al. (1993) found, in their freeze denaturation study of carp myofibrils with KCl or NaCl, that freeze denaturation above $-13°C$ is caused by the concentrated salt solution. Effect of freeze-concentration in a cellular structure was demonstrated in a phospholipid liposomal model system (Siow et al. 2007).

Reaction of Protein with Intact Lipids

There are different views in the literature on the effect of intact lipids (i.e., lipids that have not been subjected to partial or total hydrolysis or oxidation) on fish proteins. On one hand, they seem to protect proteins; on the other, they form lipoprotein complexes, which affect protein properties (Shenouda 1980, Mackie 1993). Dyer and Dingle (1961) found that lean fish (fat content less than 1%) showed a rapid decrease in protein (actomyosin) extractability when compared with fatty fish species (3–10% lipids). Therefore, they hypothesized that moderate levels of lipids may reduce protein denaturation during frozen storage. In contrast, Shenouda and Piggot (1974) observed a detrimental effect of intact lipids on protein denaturation in their study of a model system, which involved incubating lipid and protein extracted from the same fish at 4°C overnight. They showed that when fish actin (G-form) was incubated with fish polar or neutral lipids, high molecular weight protein aggregates formed. They suggested that during freezing, lipid and protein components form lipoprotein complexes, which change the textural quality of muscle tissue.

Reaction of Proteins with Oxidized Lipids

During frozen storage, lipid oxidation products cause proteins to become insoluble and harder (Takama 1974). When proteins are exposed to peroxidized lipids, peroxidized lipid–protein complexes will form through hydrophobic interactions or hydrogen bonds (Narayan et al. 1964), thus causing conformational changes in the protein. The unstable free radical intermediates of lipid peroxidation remove hydrogen from protein, forming a protein radical, which could initiate various reactions such as cross-linking with other proteins or lipids and formation of protein–protein and protein–lipid aggregates (Karel et al. 1975, Schaich and Karel 1975, Gardner 1979). Roubal and Tappel (1966) found that peroxidized protein cross-links into a range of oligomers, which are associated with protein insolubility. Careche and Tejada (1994) found that oleic and myristic acid had a detrimental effect on the ATPase activity, protein solubility, and viscosity of hake muscle during frozen storage.

Secondary products from lipid oxidation such as aldehydes react chemically with the amino groups of proteins through the formation of Shiff base adducts, which fluoresce (Leake and Karel 1985, Kikugawa et al. 1989). Ang and Hultin (1989)

suggested that formaldehyde might interact with protein side chains and form aggregates without causing cross-linking.

Lipid Oxidation and Hydrolysis

Lipids degrade by two mechanisms: hydrolysis (lipolysis) and oxidation (Shenouda 1980, Shewfelt 1981). In frozen foods, enzymes generally catalyze lipid hydrolysis. Phospholipase A and lipases from muscle tissues are responsible for the hydrolysis of phospholipids and lipids in frozen fish (Shewfelt 1981, De Koning et al. 1987). As the storage time increases and the frozen storage temperature elevates, FFAs from the hydrolysis of lipids start to accumulate (Dyer and Dingle 1961). FFAs have a detrimental effect on both the textural properties and flavor of fish.

Lipid oxidation is considered one of the major factors that limit the shelf life of frozen seafood. Fish lipids are known for their susceptibility to oxidation, particularly during frozen storage. Oxidation of PUFAs yields various oxidative products including a mixture of aldehydes, epoxides, and ketones, which give fish a rancid flavor (Gardner 1979). The low flavor threshold of most aldehydes formed during lipid oxidation means they are easily perceived by the consumer and, therefore, reduce the acceptability of the products. Rancid flavor in salmon is caused by the formation of volatile products such as (E,Z)-2,6-nonadienal (cucumber odor), (Z)-3-hexanal (green odor), and (Z,Z)-3,6-nonadienal (fatty odor) (Milo and Grosch 1996). The characteristic "seaweed" odor of fresh fish tissue results from the volatile compounds formed during rapid degradation of site-specific hydroperoxides (Josephson and Lindsey 1986). The content of lipid hydroperoxides and FFAs in salmon increases during storage, and these changes are fastest when stored at $-10°C$ (Refsgaard et al. 1998). Cod samples stored for 18 months at $-15°C$ had hepta-trans-2-enal and hepta-trans-2,cis-dienal. These compounds were described as cold storage flavor (cardboard, musty) with a very low flavor threshold (Coggins and Chamul 2004). Brake and Fennema (1999) found that the rate of decrease for thiobarbituric acid reactive substances (TBARS) was abrupt below glass transition temperature (Tg'), whereas the rates of decrease for lipid hydrolysis and peroxide values were moderate to small, respectively, in frozen minced mackerel. They suggested that the TBARS reduction rate is more diffusion limited than those for lipid hydrolysis and peroxide.

Color changes are an indicator of food quality deterioration. Nonenzymic browning occurs as a consequence of chemical reactions between peroxidizing lipids in the presence of protein. Fluorescence Schiff base adducts formed as a result of chemical reactions between tetrameric dialdehyde and amino groups of protein (Haard 1992a, 1992b). Aubourg (1998) observed a higher fluorescence ratio in a formaldehyde and fatty fish model system compared with the model for formaldehyde and lean fish. In addition to flavor and color changes, lipid oxidation products, including FFAs and aldehydes, decrease protein solubility and cause undesirable changes in the functional properties of proteins (Sikorski et al. 1976).

Aquatic species are especially rich in long-chain PUFAs and are more susceptible to lipid oxidation. As a result, various antioxidants have been experimented with by adding antioxidants to seafood during processing, thus minimizing or delaying the oxidation process and prolonging shelf life of seafood. Natural antioxidants seem to be the preferred types for recent research studies. Rosemary extract added to sea salmon mince reduced lipid oxidation during storage up to 6 months (Tironi et al. 2010) and garlic and grape seed extract have also shown to have a lipid oxidation protective effect (Yerlikaya et al. 2010). However, grape seed extract did not score well in sensory aspects for appearance, odor, and taste. Coating of fish with chitosan film has been demonstrated to be successful in effectively inhibiting lipid oxidation during frozen storage. Examples are the coating of silver carp (Fan et al. 2009) and lingcod fillet (Duan et al. 2010) with chitosan prior to frozen storage.

Lipid oxidation stability may also be achieved through feeding commercially farmed fish with a diet enriched with natural antioxidants such as tocopherol isomers (Ortiz et al. 2009). α-Tocopheryl acetate was also used as a dietary vitamin E supplement in beluga sturgeon (*Huso huso*) because it is fairly stable in the feed and only becomes active as an antioxidant after the hydrolysis of the acetate group in the fish body. It was shown to slow down lipid oxidation of the fish muscle during frozen storage (Hosseini et al. 2010).

Degradation of Trimethylamine Oxide

TMAO, a source of formaldehyde, is present naturally in many marine animals as an osmoregulator and as a means of excreting nitrogen (Hebard et al. 1982). After death, TMAO is readily degraded to DMA and formaldehyde in the presence of the endogenous enzyme (TMAOase) in the fish tissues (Bremner 1977, Hebard et al. 1982, Nielsen and Jorgensen 2004). It has been postulated that formaldehyde binds covalently to various functional groups in proteins and hence results in a deconformation of the protein, followed by cross-linking between the protein peptide chains via methylene bridges (Sikorski et al. 1976). The interaction of formaldehyde with muscle protein accelerates muscle protein denaturation (Crawford et al. 1979, Ciarlo et al. 1985, Sotelo et al. 1995). Research using both mechanical and sensory tests has shown that formaldehyde formed from the degradation of TMAO increases the firmness and decreases juiciness of mince prepared from white muscle or fillets of gadoid and nongadoid fish species (Rehbein 1988). The presence of formaldehyde also causes a noticeable decrease in the extractability of total proteins, particularly the myofibrillar group (Lim and Haard 1984, Benjakul and Bauer 2000). Ishikawa et al. (1978) suggested that depletion of TMAO accelerates the autoxidation reaction of lipids. Therefore, it is clear that the degradation of TMAO increases the toughness of muscle protein and accelerates the oxidation and hydrolysis of lipids.

Summary

During freezing, the formation of ice changes the order of water molecules in the food environment, causes dehydration and solute concentration, and thus disturbs the conformation of protein, leading to protein denaturation. Lipid degradation and enzymatic degradation of TMAO during freezing affect the

textural and sensory properties of frozen seafood. Therefore, it is important to understand the mechanisms of various biochemical and physicochemical reactions occurring during freezing and frozen storage so that the quality of frozen food can be maintained.

BIOCHEMISTRY OF DRIED, FERMENTED, PICKLED, AND SMOKED SEAFOOD

Salting, fermenting, marinating (pickling), drying, and smoking of fish and marine invertebrates increase the shelf life and develop in the products' desirable sensory properties. Extension of storage life is achieved mainly through the combined effects of

- a reduction in water activity from the addition of salt;
- a decrease in microbial load by the application of heat;
- the presence of inherent preservatives such as acetic acid;
- the use of chemical preservatives such as ascorbic acid, BHA, and BHT; and
- the antibacterial and antioxidant activities of various smoke components.

The enzymatic and spoilage processes are controlled not only by these chemical components but also by the temperature, pH, and availability of oxygen. Desirable changes in sensory properties are thus developed as a result of these carefully controlled chemical and enzymatic processes (Shewan 1944, Doe and Olley 1990, Miler and Sikorski 1990, Shenderyuk and Bykowski 1990, Perez-Villarreal 1992, Fuke 1994, Haard 1994, Sikorski and Ruiter 1994).

There are some changes in proteins. In the salting of fish, salt will penetrate slowly into the tissues, affecting the stability of the native proteins and reducing their extractability. Heavily salted fish, when compared with less salted fish, has the following disadvantages:

- More water loss due to osmosis
- Tougher texture
- Less developed flavor

It should be remembered that enzymes are also proteins, and their activities are affected by salt concentration.

Another effect of salting is the changes in texture of the final product. It is believed that the calcium and magnesium ions present as impurities in salt may penetrate the fish, giving rise to a soft, "mushy" texture in the fillet. This may be undesirable for most salted fish, but this effect is considered highly desirable in some Chinese salted products (tender salted threadfin, tender salted mackerel, and others), and Scandinavian products (such as kryddersild, tidbit, and gaffelbiter) (Shewan 1944). Salting of whole fish should be controlled precisely, as overripening will result in excessively soft products with sensory properties that are undesirable to most consumers. However, changes in salted fish fillets depend mostly on endogenous muscle proteases.

Fermented fish paste and sauce are popular products prepared and consumed in southern China and Southeast Asian countries as a source of nutrients and as condiments. Generally, whole fish or shrimp are used as the raw materials for the preparation of these products. It is believed that extensive proteolysis occurs under carefully controlled conditions. It is difficult to differentiate the endogenous and bacterial actions of proteolysis because of the use of whole fish or shrimp and the way these products are produced. Sikorski and Ruiter (1994) summarized some of the work on proteolysis in fermented fish products. Cathepsins A and C as well as trypsin-like enzyme are endogenous proteases that appear to contribute to fish sauce production both in yield and quality (Orejana and Liston 1982, Rosario and Maldo 1984, Raksakulkthai et al. 1986).

Chiou et al. (1989) reported that cathepsin D-like and aminopeptidase activities release a large amount of free amino acids during roe processing and contribute to the flavor. In the drying of squid, endogenous cathepsin C appears to contribute to desirable qualities (texture and flavor) of traditional products (Haard 1983). Simpson and Haard (1984) reported that added trypsin appears to be a key enzyme contributing to the texture and flavor of matjes herring.

Marinating fish (mainly herring) by means of salt and acetic acid is one of the oldest ways of preserving food in European countries. The acid condition of the marinades, with pH 4–4.5, makes the tissue cathepsins much more active. This results in the degradation of muscle proteins into peptides and amino acids. This permits the marinade to create the proper flavor and texture in the product (Meyers 1965).

Smoke curing means the smoking of presalted fish. The action of the smoke constituents produces a unique smoky odor, taste, and color. The process also contributes to the tenderizing action on the fish tissue. In cold-smoked fish, this tenderization is caused predominately by the action of endogenous proteolytic enzymes because of their activity at such ambient temperatures.

BIOCHEMISTRY OF THERMAL-PROCESSED PRODUCTS

Exposure of the fish to elevated temperatures is detrimental to tissue structure, and results in very undesirable effects (Haard 1994). Extreme texture softening in fish has been attributed to cysteine proteases acting on the fish muscle at elevated temperatures (Konegaya 1984). Heat-stable alkaline proteases and neutral proteases (modori or gel-degradation) are active when the temperature reaches 60–70°C (Lin and Lanier 1980, Kinoshita et al. 1990). Degradation of connective tissue of mackerel appears to be associated with muscle proteases and pyloric ceca collagenase (Pan et al. 1986).

The rate of oxidation of desirable myoglobin and oxymyoglobin of the red muscles of tuna to brown metmyoglobin depends on the species of the fish and on the storage temperature (Mattews 1983). Color deterioration in iced and frozen stored bonito, yellowfin, and skipjack tuna caught in Seychelles waters was demonstrated in this study.

Food biochemistry plays a role in the production of thermally processed seafood. During the canning of seafood, it is a common practice to precook the raw materials, for example,

fish and crustaceans. The accompanying thermal treatment coagulates the proteins in the muscles for easy handling and removal of nonedibles as well as for quality inspection in the later steps. It also inactivates the enzymes that can cause biochemical deterioration of the raw materials, when exposed to elevated temperatures and extended storage times. For example, in manufacturing canned tuna, the fish is precooked and permitted to cool completely, sometimes overnight, before the following steps: (1) removal of skin, bones, dark meats, and viscera and (2) inspection for the presence of defects, for example, honeycombed and/or burnt tissues.

It should be noted that honeycombed tissues are only detectable in the cooked fish. In the production of canned crabmeat, the precooked crab is cooled before the extraction of crabmeat. Without precooking to coagulate the crabmeat, it is almost impossible to separate the crabmeat from its shell efficiently. The precooking also inactivates those enzymes that can degrade the quality of the product. This is especially important in products like crab and shrimp, as the deteriorating enzymes can act very quickly on these tissues at elevated temperatures. However, there are exceptions where the raw fish is not precooked in order to preserve the premium quality. This includes the production of canned salmon, where sections of raw salmon with skin and bones are stuffed into the can before sealing and processing.

Thermal processing such as mild heating also is applied in the production of some dried seafood products such as fish, shrimp, and squid. The heating process inactivates the deteriorating enzymes in the raw materials. This stops the enzymatic reactions from occurring during drying or dehydrating processes that expose the intermediate products to ambient or elevated temperatures for extended periods. For example, in the production of dried, shaved bonito, the raw bonito is first precooked in brine before the processes of recovery of loin tissues, drying to coagulate the tissues, and shaving of the dried product. Without this precooking process, the fish tissue will deteriorate during the long drying process. For dried shrimp, the majority of the product is produced with the precooking process to inactivate the deteriorating enzymes before drying or dehydrating. However, a small amount of dried shrimp is produced without precooking to produce specialty products. For dried squid, it is usually produced without precooking to develop the unique flavor from enzymatic reactions during drying or dehydration. However, a small amount is produced by precooking the product prior to the drying process.

Thermal processing of seafood such as canning and mild heat treatment attempts to produce a final product with long shelf life and favorable consumer acceptance. For more details, refer to the review by Aubourg (2001).

Fish Collagen

Soottawat Benjakul, Sitthipong Nalinanon, and Fereidoon Shahidi

Abstract: Fish collagen has gained increasing interest as the alternative for mammalian counterpart. It can be generally produced from by-products generated during processing of fish and invertebrates. The potential raw materials include skin, bone, scale, and so on. Types and molecular properties of collagen vary with the source, habitat of fish, extraction process, and other factors. In general, collagen can be extracted from collagenous materials at low temperature with the aid of various acids to avoid thermal denaturation. To increase the extraction yield, pepsins from mammalian and fish origins, which specifically cleave at telopeptide region, have been used successfully without the changes in molecular properties. Fish collagen can be of food, biomedical, and pharmaceutical applications.

INTRODUCTION

Collagen is the fibrous protein of animal connective tissue, contributing to the unique physiological functions of tissues in skins, tendons, bones, cartilages, and so on and is associated with toughness in mammalian muscle (Foegeding et al. 1996, Ogawa et al. 2003, Muyonga et al. 2004, Yan et al. 2008, Kittiphattanabawon et al. 2010a). The collagen fibers are essentially inextensible and, therefore, provide mechanical strength and also allow flexibility between various organs of the body (Bailey et al. 1998).

Collagen is widely used in food, biomedical, pharmaceutical, and cosmetics, and its consumption has been increasing along with the development of new industrial application (Nalinanon et al. 2007, Regenstein and Zhou 2007, Woo et al. 2008). Collagen exhibits biodegradability, weak antigenecity, and superior biocompatibility compared with other natural polymers, such as albumin and gelatin (Lee et al. 2001). Generally, commercial collagens are produced from bovine and porcine hides and bones. Currently, the increasing attention of alternative sources for replacement of mammalian collagen has been paid, especially from seafood processing by-products. Fish collagen can be used for Halal and Kosher products for Muslim and Jewish communities, respectively. Because of the outbreak of bovine spongiform encephalopathy and bird flu, the increasing demand of fish collagen has been gained (Jongjareonrak et al. 2005, Nalinanon et al. 2007, 2008, Regenstein and Zhou 2007, Duan et al. 2009, Kittiphattanabawon et al. 2010a). Collagen can be extracted from fish skin, scale, and bone. Collagen is also found in the body walls and cuticles of invertebrates (Meena et al. 1999). With the appropriate extraction technology, collagen from fish or aquatic animals can be used as the potential alternative for mammalian counterpart.

Figure 20.1. Arrangement of collagen fibril in collagen fiber. (**A**) Amino acid sequence of a collagen polypeptide. (**B**) Collagen polypeptide. (**C**) Tropocollagen. (**D**) Collagen fibril.

COLLAGEN COMPOSITION AND STRUCTURE

Collagen is typically used as a generic term to cover a large family of distinct proteins, each with specific structures, functions, and tissue distributions in the extracellular matrix (Ramshaw et al. 2009). The collagen monomer is a long cylindrical protein about 2800 Å long and 14–15 Å in diameter (Foegeding et al. 1996). Collagen is constructed from tropocollagen, a rod-shaped protein consisting of three polypeptides unit (called α-chains) intertwined to form a triple-helical structure. Each α-chain coils in a left-handed helix with three residues per turn, and the three chains are twisted right-handed to form the triple helix (Wong 1989) (Fig. 20.1). The three chains are held together primarily by hydrogen bonding between adjacent –CO and –NH group

(Wong 1989, Lee et al. 2001). At least 19 types of collagen designated types I–XIX have been reported (Bailey et al. 1998, Lee et al. 2001, Woo et al. 2008). Different α-chains, designated α1, α2, or α3, within the same type of collagen differ in their amino acid composition. The distribution of α1-, α2-, and α3-chains in collagen molecules varies depending on the specific genetic variants (Xiong 1997). The most common collagen is type I collagen. It contains two α1(I)-chains and one α2(I)-chain, which has different amino acid sequence and composition. Each chain has a molecular mass about 100,000Da, yielding a total molecular mass of about 300,000 Da of collagen (Foegeding et al. 1996).

Type I collagen is the major of epimysium. Both types I and III are present in the perimysium in large amounts, whereas types II, IV, and V are primary species in epimysium (Table 20.1) (Xiong 1997). Types I, II, and III collagen as well as types V

Table 20.1. Collagens and Their Distribution

Type	Peptide Chains[a]	Molecular Composition	Occurrence
I	α1, α2	$[\alpha1(I)]_2\ \alpha2(I)$	Skin, tendon, bone, muscle (epimysium)
II	α1	$[\alpha1(II)]_3$	Intervertebral disc, cartilage
III	α1	$[\alpha1(III)]_3$	Fetal skin, cardiovascular vessel, uterus, synovial membranes, inner organ, muscle (perimysium)
IV	α1, α2	$[\alpha1(IV)]_3(?)$ [b]	Basement membrane, kidney glomeruli, lens capsule, glomeruli
V	AA, αB, αC (?)	$[\alpha B]_2\alpha A$ or $(\alpha B)_3\ +$ $(\alpha A)_3$ or $(\alpha C)_3(?)$	Placental membrane, cardiovascular system, lung, muscle (endomysium)

Sources: Wong (1989) and Belitz et al. (2004).
[a]Since the α-chains of various types of collagen differ, the are called α1(I), α1(II), αA, etc.
[b](?) Not completely elucidated.

and XI are built up of three chains and all are composed of the continuous triple-helical structure (Lee et al. 2001). Types I, II, III, and V are also called as fibril-forming collagens and have large sections of homologous sequences independent of species (Timpl 1984). Foegeding et al. (1996) reported that types IV and III collagens contain oxidizable cysteine residues and is rich in hydroxyproline and hydroxylysine. In type IV collagen (basement membrane), the triple-helical conformation is interrupted with large nonhelical domains as well as with the short nonhelical peptide interruption (Lee et al. 2001). Like type IV collagen, type V collagen is rich in hydroxyproline and hydroxylysine but contains no cysteine. Type VI is microfibrillar collagen, and type VII is anchoring fibril collagens (Samuel et al. 1998).

Based on its macromolecular structures, collagen can be divided into three major groups: (a) striated fibrous collagen, which includes types I, II, and III collagen, (b) nonfibrous collagen, which contains type IV or basement membrane collagen, and (c) microfibrillar collagen, which encompasses types VI and VII (the matrix microfibrils), types V, IX, and X (the pericellular collagen), and types VIII and XI, which are yet unclassified (Xiong 1997). Fibril-associated collagens (types IX, XI, XII, and XIV) have small chains, which contain some nonhelical domains (Lee et al. 2001). Each is characterized by having the triple-helical motif as part of its structure (Ramshaw et al. 2009).

In the extracellular space, collagen molecules align themselves into microfibrils in quarter stagger array. Cross-linking is initiated and larger diameter fibrils are formed either by the addition of microfibrils or by association with other fibrils (McCormick 1994). During maturation or aging, collagen fibers can be strengthened and are stabilized primarily by covalent cross-linkages (Belitz et al. 2004). Thus, the cross-links confer mechanical strength to collagen fiber. Belitz et al. (2004) proposed that cross-link formation involves (i) enzymatic oxidation of lysine and hydroxylysine to the corresponding ω-aldehydes, (ii) conversion of these aldehydes to aldols and aldimines, and (iii) stabilization of these primary products by additional reduction or oxidation reactions. The cross-linking stereochemistry derives from the reaction of specific peptidyl aldehydes, in the NH_2- and COOH-terminal nonhelical peptide, with vicinal ε-amino groups of specific peptidyl residues of Lys and Hyl, located in the triple-helical regions of molecules (Mechanic et al. 1987). Intermolecular cross-links are confined to the end-overlap region involving a lysine aldehyde in the telopeptide of one chain and a hydroxylysine of an adjacent chain (Foegeding et al. 1996). Furthermore, Avery and Bailey (2005) proposed that the slow turnover of mature collagen subsequently allows accumulation of the products of the adventitious nonenzymic reaction of glucose with the lysines in the triple helix to form glucosyl lysine and its Amadori product. These products are subsequently oxidized to a complex series of advanced glycation end-products; some of which are intermolecular cross-links between the triple helices, rendering the fiber too stiff for optimal functioning of the collagen fibers, and, consequently, of the particular tissue involved.

The number of cross-links in collagen increase with increasing age of the animal (Zayas 1997, Belitz et al. 2004). Most connective tissue in fish is renewed annually, and highly cross-linked protein is not generally found in fish (Foegeding et al. 1996). Collagenous tissue from older animals with more cross-linkages is more resistant to swelling and has a lower water-holding capacity (Zayas 1997). The steady increase in mature collagen cross-linking is due to progressive and ongoing cross-linking reactions that occur within fibrillar collagen and with the slowing of collagen synthesis rates as animals reach maturity (McCormick 1994). Collagen from young animals is more easily solubilized and produces structures with low tensile strength. In contrast, collagen from old animals is difficult to solubilize and produces a structure with high tensile strength (Miller et al. 1983). In starving fish, the sarcoplasmic and myofibrillar proteins undergo gradual degradation, while the connective tissues are not utilized, or extra collagen is even deposited in the myocommata and in the skin (Sikorski et al. 1990). Thus, the toughening process in fish seems to be much more reversible than that of higher animals, where the amount of cross-linking increases with age (Regenstein and Regenstein 1991). Foegeding et al. (1996) reported that starving fish produce more collagen, especially collagen with a greater degree of cross-linking, than the fish that are well fed. Furthermore, collagens in myocommata are thickened with more intermolecular cross-links of collagen during starvation (Love et al. 1976).

Glycine represents nearly one-third of the total residues, and it is distributed uniformly at every third position throughout most of the first collagen molecule. The repetitive occurrence of glycine is absent in the first 14 amino acid residues from N-terminus and the first ten residues from the C-terminus, in which these end portions are termed "telopeptides" (Foegeding et al. 1996). The presence of glycine at every three residues is a critical requirement for the collagen superhelix structure (Regenstein and Zhou 2007). Glycine contains no side chain, which allows it to come into the center of the superhelix without any steric hindrance to form a close packing structure (Te Nijenhuis 1997). The triple helix of collagen assembled from specific polypeptide chain (α-chain) with the Gly-X-Y repeat and contain frequent occurrence of proline (Pro) and hydroxyproline (Hyp) in the X- and Y-positions, respectively (Johnston-Banks 1990, Xu et al. 2002). Hydroxyproline is located at Y-position, as is hydroxylysine, while proline can be found in either the X- or Y-positions (Johnston-Banks 1990). The distribution of polar and nonpolar residues in the X-position determines the ordered aggregation of molecules into fibrils (Xiong 1997). The segments of the polypeptide chain consisting of repeating triplets with imino acid residues are the nonpolar regions, and the segments containing Gly-X-Y triplets without imino acids are mostly polar (Wong 1989). Collagen is a hydrophilic protein because of the greater content of acidic, basic, and hydroxylated amino acid residues than lipophilic residues. Therefore, it swells in polar liquids (Johnston-Banks 1990).

The amino acid composition of collagen is unique. The collagens are rich in glycine, proline and alanine, and contained low or no cysteine and tryptophan (Table 20.2). Relatively low contents of tyrosine and histidine are reported in collagen. Two amino acids that are not commonly present in other proteins include hydroxyproline and hydroxylysine (Wong 1989). The amino acid composition of collagen is nutritionally unbalanced,

[a]Imino acids include proline and hydroxyproline.

which is almost devoid of tryptophan. Fish muscle, skin, bone, and scale collagen differ from bovine and porcine hide collagens in having significantly higher contents of seven essential amino acids (Sikorski et al. 1990). Collagen is the only protein that is rich in hydroxyproline (up to 10% in mammalian collagen) (Sikorski et al. 1990). On the other hands, hydroxyproline is present in negligible amounts in other proteins, thus it is often used as a measure of collagen content in foods (Foegeding et al. 1996). Proline and hydroxyproline, imino acids, contents vary with species and their living habitat (Foegeding et al. 1996, Jongjareonrak et al. 2005, Kittiphattanabawon et al. 2005). Fish collagens contain less imino acids than do mammalian counterpart (Table 20.2). Lower content of imino acids is generally found in cold-water fish, compared with warm-water fish. Imino acids contribute to the stability of helix structure of collagen (Ikoma et al. 2003, Jongjareonrak et al. 2005). Pyrrolidine rings of proline and hydroxyproline impose restrictions on the conformation of the polypeptide chain and help to strengthen the triple helix (Wong 1989, Bae et al. 2008). The hydroxyl group of the hydroxyproline plays a role in stabilizing the helix by interchain hydrogen bonding via a bridging water molecule as well as direct hydrogen bonding to a carbonyl group (Wong 1989). Interchains between α-chains of collagen, in which hydroxyproline is involved in bondings are illustrated in Figure 20.2. Hydroxylysine of 6–20 residues/1000 residues is found in collagens,

suggesting the partial cross-linking of collagen via covalent bond (Mechanic et al. 1987). Transition temperature of collagen from tropical fish is generally higher than that from cold- or temperate-water fish (Muyonga et al. 2004, Nalinanon et al. 2010). Differential scanning calorimetric study revealed the differences in maximal transition temperature (T_m) among collagen from different sources (Table 20.5). Therefore, collagen from different sources might have the different molecular properties due to the difference in imino acid content and cross-linking.

Collagen contains carbohydrates such as glucose and galactose. Other sugars are also found in some fish and invertebrate collagens. These are attached to hydroxylysine residues of the peptide chain by O-glycosidic bonds. The presence of 2-O-α-D-glucosyl-O-β-D-galactosyl-hydroxylysine and of O-β-D-galactosyl-hydroxylysine has been confirmed (Belitz et al. 2004). Some fish and invertebrate collagens also contain small amounts of arabinose, xylose, and ribose residues (Kimura 1972). These hydroxylysine-linked carbohydrates may have an impact on the structure of the fibrils in the invertebrate collagen (Sikorski et al. 1990).

ISOLATION OF COLLAGEN

Isolation of collagen is generally separated into three main steps, including sample preparation, extraction, and recovery.
Figure 20.2. Contribution of hydroxyproline in hydrogen bonding between collagen polypeptides.

Generally, collagen can be extracted from fish skin, bone, scale, and so on. Those raw materials have been prepared by cleaning, size reduction, followed by appropriate pretreatment, prior to extraction. The extraction is carried out by the aid of acid, in which the resulting collagen is termed "acid-soluble collagen, ASC." Because of the lower yield of collagen obtained from this process, pepsin-aided process has been developed to maximize the extraction yield and the resultant collagen is named "pepsin-soluble collagen, PSC." Flow chart for the preparation of ASC and PSC is shown in Figure 20.3. All procedures are performed at low temperature (4°C) to avoid the thermal denaturation. All processes used for collagen extraction directly affect the extraction yield and properties of collagen obtained. The conditions for the extraction of collagen from different sources can be summarized in Table 20.4.

PREPARATION OF RAW MATERIALS

In general, the raw material for collagen preparation contains a number of contaminants including noncollagenous proteins, lipids, and pigments, and so on. Calcium or other inorganic matters are found in scale and bone. One or several pretreatments are used to remove the contaminants and increase the purity of extracted collagen. The removal of residual meats and cleaning are performed before further chemical pretreatments. Size reduction of raw material is also useful to facilitate the contaminant removal and collagen extraction. To remove noncollagenous proteins and pigments, alkaline pretreatment is used (Nagai and Suzuki 2002, Kittiphattanabawon et al. 2005, Hwang et al. 2007, Duan et al. 2009, Zhang et al. 2009, Benjakul et al. 2010). NaOH at a concentration of 0.1 M is widely used. However, NaCl and H_2O_2 have also been used to remove noncollagenous proteins and pigments, respectively (Wang et al. 2007, Zhuang et al. 2009). Some raw materials such as bones from carp (Duan et al. 2009) and bigeye snapper (Kittiphattanabawon et al. 2005) and scale from carp (Duan et al. 2009) contain high amount of

calcium. Those raw materials are effectively decalcified by using ethylenediaminetetraacetic acid (EDTA) because of its chelating function. The decalcification can be also achieved by using inorganic acid, especially hydrochloric acid. As a consequence, the porous decalcified raw material with increased surface area can be readily subjected to collagen extraction.

The yield and properties of collagen would be influenced by the source of the raw material, the nature and concentration of acid or alkali used during pretreatment and the temperature and time of pretreatment and extraction (Regenstein and Zhou 2007). Prior to collagen extraction, skin, scale, and bone are generally subjected to noncollagenous protein removal. Thereafter, pretreated raw material is defatted or the pigments in the skin can be bleached to lower the color. In shark skin, different process was proposed by Yoshimura et al. (2000). For the alkali–acid extraction of collagen from the skin of great blue shark (*Prionace glauca*), a pretreatment with 0.5 or 1 M NaOH containing 15% Na_2SO_4 for 5 days at 20°C was required prior to acid extraction. For the alkaline direct extraction, a treatment with 0.5 M NaOH containing 10% NaCl at 4°C for 20–30 days was implemented.

EXTRACTION

Acid Solubilization Process

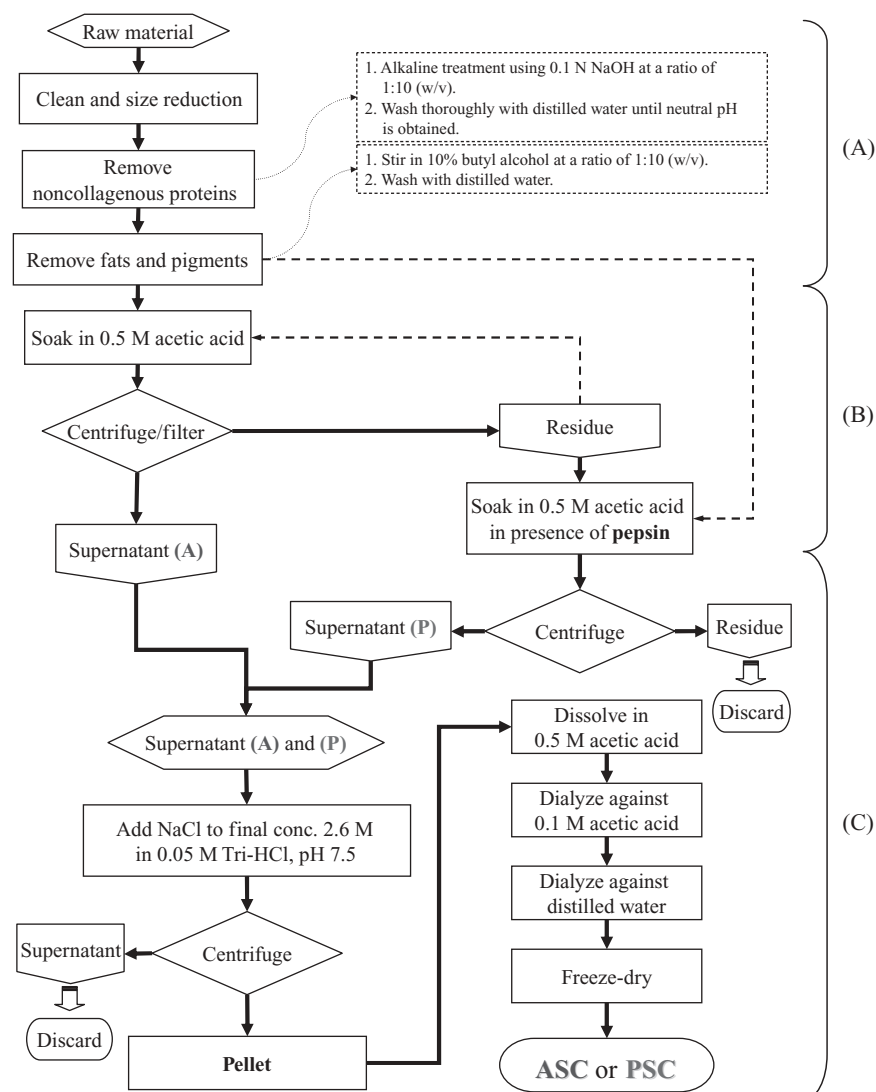
The acid solubilization process has been widely used for collagen preparation. The collagen can be extracted using acid solution and the collagen obtained is referred to as "acid-soluble collagen, ASC." Extraction is conducted using acidic condition, in which the positive charge of collagen polypeptides becomes dominant. As a consequence, the enhanced repulsion among tropocollagen can be achieved, leading to the increased solubilization. Generally, tropocollagen is still in the form of triple helix with negligible changes. Fourier transform infrared (FTIR) spectra of collagens from the skins of carp and brownbanded bamboo shark and arabesque greenling extracted with acetic acid apparently revealed the triple-helical structure of collagen


Figure 20.3. Flow chart for the preparation of acid soluble collagen (ASC) and pepsin soluble collagen (PSC). All procedures are performed at 4°C. (**A**) Preparation of raw material. (**B**) Extraction. (**C**) Recovery.

(Duan et al. 2009, Nalinanon et al. 2010, Kittiphattanabawon et al. 2010a). Collagen from total tissue can be isolated by direct extraction with organic acids (acetic, chloracetic, citric, lactic) or inorganic acid (hydrochloric). The yield of extracted collagen depends on the animal species used and the age and parameters of extraction (Skierka and Sadowska 2007). Collagen extraction from different species has been performed using acetic acid. Collagen extraction is generally achieved by 0.5 M acetic acid treatment at 4°C for 24–48 hours. Compared to simply prolonging the extraction time, the use of several consecutive extraction may get better ASC yield (Sadowska et al. 2003, Regenstein and Zhou 2007, Skierka and Sadowska 2007). Nalinanon et al. (2008) found that ASC yield from the skin of threadfin bream was increased from 12.32% to 34.90% (based on hydroxyproline content), when extended the extraction time from 6 to 48

hours. The similar result was observed in collagen extraction from bigeye snapper skin, in which the yield increased from 7.3% to 9.3% (based on hydroxyproline content) with increasing extraction time from 24 to 48 hours (Nalinanon et al. 2007). Increasing the concentration of acetic acid used from 0.1 to 0.5 M resulted in the increased yield of collagen extracted from minced cod skin, from 52% to 59% (dry weight). Re-extraction of residual matter with 0.5 M acetic acid can be performed to increase the yield of ASC, particularly in carp bone (Duan et al. 2009), bigeye snapper skin and bone (Kittiphattanabawon et al. 2005).

Skierka and Sadowska (2007) studied the influence of different acids on the extractability of collagen from the skin of Baltic cod (*Gadus morhua*). The maximal yield of collagen extracted with 0.5 M citric acid and acetic or lactic acids was 60% and 90%
Figure 20.4. Collagen extraction with the aid of pepsin in 0.5 M acetic acid at 4°C. (**A**) Collagenous tissue degradation. (**B**) The cleavage of telopeptide region of collagen by pepsin. (**C**) Pepsin soluble collagen (PSC) or atelocollagen.

(based on hydroxyproline content), respectively, whereas collagen extracted with 0.15 M HCl had the yield of only 18%. The positively charged amine groups of protein can bind with anions (Cl⁻), reducing electrostatic repulsive forces between charged groups. As a consequence, the structure of collagenous fibers is tightening, the ability of bonding water decreases, and the solubility of collagen is, therefore, reduced (Skierka and Sadowska 2007).

Pepsin Solubilization Process

Generally, typical acid solubilization process renders a low yield of collagen. To tackle the problem, pepsin has been applied because it is able to cleave peptides specifically in telopeptide re-

gion of collagen, leading to increased extraction efficiency (Fig. 20.4; Nagai et al. 2002a, Nalinanon et al. 2007). Use of pepsin as the aid for collagen extraction is a potential method for several reasons: (1) some of noncollagenous proteins are hydrolyzed and are easily removed by salt precipitation and dialysis, improving collagen purity; (2) hydrolyze those components and telopeptides of collagen to make the sample ready to solubilize in acid solution, resulting in improvement of extraction efficiency; (3) reduce antigenicity cause by telopeptide in the collagen which serve as the major problem in food and pharmaceutical applications (Werkmeister and Ramshaw 2000, Lee et al. 2001, Lin and Liu 2006, Cao and Xu 2008). Pepsin, particularly pepsin from porcine stomach, has been used to maximize the extraction efficiency of collagen from several species such as largefin

Table 20.3. Band Intensity Ratios of Cross-Linked Chain to Total Monomer Chains in Collagen from the Skin of Several Sources

Collagens	Sources	$\alpha 1/\alpha 2$	$\beta/(\alpha 1+\alpha 2)$	$\gamma/(\alpha 1+\alpha 2)$
ASC	Calf [a]	ND	1.26	0.75
	Black drum [a]	ND	1.59	1.32
	Sheepshead sea bream [a]	ND	1.30	0.62
	Deep-sea redfish [b]	2.47	1.52	1.10
PSC	Black drum [a]	ND	0.50	0.23
	Sheepshead sea bream [a]	ND	0.84	0.51
	Deep-sea redfish [b]	2.15	1.03	0.19

langbarbel catfish (Zhang et al. 2009), seaweed pipefish (Khan et al. 2009), deep-sea redfish (Wang et al. 2007), brownstripe red snapper (Jongjareonrak et al. 2005), ocellate puffer fish (Nagai et al. 2002a), skate (Hwang et al. 2007), brownbanded bamboo shark (Kittiphattanabawon et al. 2010a), blacktip shark (Kittiphattanabawon et al. 2010c), cuttlefish (Nagai et al. 2001), octopus (Nagai et al. 2002b), scallop (Xuan Ri et al. 2007), paper nautilus (Nagai and Suzuki 2002), and common minke whale (Nagai et al. 2008). Skierka and Sadowska (2007) found that pepsin treatment of Baltic cod skin in acetic acid shortened the extraction time to 24 hours and the solubility of collagen, after pepsin digestion increased from 55% to 90%. After ASC extraction, the residues that represent the cross-linked molecules are further extracted in the presence of pepsin. The collagen obtained with pepsin treatment is referred to as "pepsin-soluble collagen, PSC" (Nagai et al. 2001, Ogawa et al. 2003, Nalinanon et al. 2007) or "atelocollagen" (Lee et al. 2001, Ikoma et al. 2003). The use of pepsin as the aid of collagen extraction resulted in the increased yield (see Table 20.4). The yield of extracted collagen also increased with increasing preswelling time and pepsin treatment time. From the skin of bigeye snapper (*Priacanthus tayenus*) subjected to preswelling with 0.5 M acetic acid and subsequent pepsin hydrolysis, those treated with these two steps with longer time led to the increase in yield of collagen extracted (Nalinanon et al. 2007). At the same preswelling time and hydrolysis time, bigeye snapper pepsin (BSP) exhibited greater extracting ability than did porcine pepsin. However, the highest yield (∼65%) for collagen extraction from the skin of bigeye snapper was found when BSP was added with a reaction time of 48 hours, regardless of preswelling time (Nalinanon et al. 2007). Swollen skin, which was pretreated with acetic acid, possibly had a porous and loose structure caused by charge repulsion. As a result, the penetration of pepsin into the skin matrix could be enhanced. Thus, hydrolytic reaction of pepsin toward collagen was augmented. Miller (1972) proposed that the mechanism whereby the proteolytic activity of pepsin alters the solubility properties of cartilage collagen involves the degradation of the nonhelical region, thus effectively eliminating a site of intermolecular cross-linking. Drake et al. (1966) reported that most of intra- and intermolecular cross-links found in collagen occur through the telopeptide

region. Some of the telopeptides of calfskin tropocollagen are vulnerable to pepsin action, since intramolecular cross-links are broken on pepsin digestion and fragments comprising a small fraction of the molecule (approximately 1%) become dialyzable (Drake et al. 1966). Pepsin treatment for collagen extraction has the impact on the proportion of compositions. In general, β- and γ-chains, dimmer, and trimer in PSC are decreased as compared with those found in ASC. Cleavage of telopeptide region more likely results in the conversion of cross-links, such as β- and γ-chains, to the α-chain, which can be of ease for extraction. The band intensity ratios of $\alpha 1$-chain to $\alpha 2$-chain and cross-linked chain (trimer form, γ, or dimmer form, β) to total monomer chain ($\alpha 1 + \alpha 2$) in collagens are shown in Table 20.3. Nalinanon et al. (2007) reported that higher molecular-weight (MW) components, including γ-chain, were found to a greater extent in ASC extracted from the skin of bigeye snapper than in PSC. Ogawa et al. (2003) found that the intra- and/or intermolecular cross-linking of collagens, β and γ components, were richer in ASC than in PSC for collagens from the skin of black drum and sheepshead sea bream. Similar results were also reported in collagens extracted from deep-sea redfish (Wang et al. 2007). Those high-MW components might be degraded to smaller components, such as β, $\alpha 1$, or $\alpha 2$, by pepsin action. Pepsin removes the cross-link-containing telopeptide, and the concomitantly one β-chain is converted to two α-chains (Nagai et al. 2001, Wang et al. 2007). Similar changes were also found in acid-solubilized calfskin tropocollagen when treated with pepsin. Native calfskin tropocollagen consisted of α:β:γ at a ratio of 32:65:3, whereas the components of pepsin-treated tropocollagen were changed to 72:23:3 (Drake et al. 1966). Therefore, the yield of collagen extraction was significantly increased because of the improvement of collagen extractability by pepsin (Ogawa et al. 2003, Nalinanon et al. 2007, Wang et al. 2007, Nalinanon et al. 2008, Benjakul et al. 2010).

Generally, commercial pepsin used for collagen extraction is isolated from porcine stomach. Owing to the limitation of porcine pepsin mostly associated with the religious constraint, pepsins from fish origin including bigeye snapper (Nalinanon et al. 2007), albacore tuna (Nalinanon et al. 2008), and tongol tuna (Nalinanon et al. 2008, Benjakul et al. 2010) have been used as the potential aid for collagen extraction from fish skin.

Nalinanon et al. (2007) reported that the addition of BSP at a level of 20 kUnits/g of defatted skin resulted in an increased content of collagen extracted from bigeye snapper skin. The yields of collagen from bigeye snapper skin extracted for 48 hours with acid and with BSP were 5.31% and 18.74% (dry basis), respectively. With preswelling in acid for 24 hours, collagen extracted with BSP at a level of 20 kUnits/g of defatted skin for 48 hours had a yield of 19.79%, which was greater than that of collagen extracted using porcine pepsin at the same level (13.03%). When tuna pepsin (10 units/g defatted skin) was used for collagen extraction from the skin of threadfin bream for 12 hours, the yield of collagen increased by 1.84- to 2.32-fold and albacore pepsin showed the comparable extraction efficacy to porcine pepsin (Nalinanon et al. 2008). Recently, PSCs from the skin of two species of bigeye snapper, *P. tayenus* and *Priacanthus macracanthus*, were extracted with the aid of tongol tuna (*Thunnus tonggol*) pepsin and porcine pepsin (Benjakul et al. 2010). Yields of PSCs extracted from the skin of *P. tayenus* with the aid of porcine pepsin (T-PP) and tongol tuna pepsin (T-TP) were 77.4 and 87.3 g kg^{-1} (based on wet weight of skin), respectively, while those of PSCs extracted from the skin of *P. macracanthus* with the aid of porcine pepsin (M-PP) and tongol tuna pepsin (M-TP) were 70.6 and 72.9 g kg^{-1}, respectively. For the same pepsin used, *P. tayenus* skin gave a higher yield than *P. macracanthus* skin. When the same skin was used for collagen extraction, tongol tuna pepsin treatment resulted in the higher yield (Benjakul et al. 2010). Therefore, tuna pepsin showed higher efficiency in collagen extraction. Pepsin from different sources might have a different cleavage site on the collagen. As a result, the peptides in the telopeptide region, which is susceptible to hydrolysis, were hydrolyzed to different degrees (Nalinanon et al. 2008, Benjakul et al. 2010). In addition, collagen from different sources was probably cleaved by the same pepsin in different ways (Benjakul et al. 2010). Furthermore, collagen from the two skins may have some differences in configuration and amino acid sequence. Fish pepsins used for collagen extraction from several sources exhibited the comparable extraction efficacy to porcine counterpart. Therefore, fish pepsin could be used as a replacer of mammalian pepsin.

The extraction conditions for ASC and PSC from different sources and their yield, type, and molecular compositions are summarized in Table 20.4.

Recovery of Collagen

After extraction, the collagen is generally recovered by salt precipitation prior to dialysis and freeze-drying. The collagen solution is generally precipitated by adding NaCl to a final concentration of 2.6 M in the presence of 0.05 M tris(hydroxylmethyl)aminomethane, pH 7.5 (Nagai and Suzuki 2000, Jongjareonrak et al. 2005, Kittiphattanabawon et al. 2005, Nalinanon et al. 2007, Benjakul et al. 2010). However, the concentrations of NaCl used for collagen precipitation in different methods are varied from 0.9 to 2.6 M. This can be adjusted to maximize the collagen recovery and removal of impurities. The resultant precipitate is then collected by centrifugation. The pellet is dissolved in 0.5 M acetic acid with minimal volume

prior to dialysis against 0.1 M acetic acid and distilled water. The dialysate is finally freeze-dried and the powder obtain is used as collagen. Collagen can be isolated from fish skin, bone, and scale (Nomura et al. 1996, Nagai et al. 2002a, Ikoma et al. 2003, Mizuta et al. 2003, Muyonga et al. 2004, Ogawa et al. 2004, Nalinanon et al. 2007, Nalinanon et al. 2008). Nagai and Suzuki (2000) extracted type I collagen from underutilized resources including fish skin, bone, and fin with varying yields as follows: (1) skin collagen: 51.4% (Japanese sea bass), 49.8% (chub mackerel), and 50.1% (bullhead shark); (2) bone collagen: 42.3% (skipjack tuna), 40.7% (Japanese sea bass), 53.6% (ayu), 40.1% (yellow sea bream), and 43.5% (horse mackerel); (3) fin collagen: 5.2% (Japanese sea bass acid-soluble collagen) and 36.4% (Japanese sea bass acid-insoluble collagen) on the dry basis. Kittiphattanabawon et al. (2005) extracted ASC from the skin and bone of bigeye snapper (*P. tayenus*) with the yields of 10.94% and 1.59% on the basis of wet weight, respectively. The yield of ASC from the skins of young and adult Nile perch (*Lates niloticus*) extracted using 0.5 M acetic acid and precipitation with 0.9 M NaCl were 63.1% and 58.7% (on a dry weight basis), respectively (Muyonga et al. 2004). Sadowska et al. (2003) extracted the collagen from the skins of Baltic cod (*G. morhua*). The use of a one-stage, 24-hour extraction of whole skins with acetic at ratio of material to solvent of 1:6, yielded 20% collagen. Using three consecutive 24-hour extractions of whole skins with citric acid, 85% of collagen protein could be separated. Recently, ASC and PSC from the skin of brownbanded bamboo shark (*Chiloscyllium punctatum*) were isolated and characterized by Kittiphattanabawon et al. (2010a). The yield of ASC and PSC were 9.38% and 8.86% (wet weight basis), respectively. Collagen from the outer skin of cuttlefish (*Sepia lycidas*) was extracted by Nagai et al. (2001). The initial extraction of the cuttlefish outer skin in acetic acid yielded only 2% of collagen (dry weight basis). On subsequent digestion of the residue with 10% pepsin (w/v), a solubilized collagen (PSC) was obtained with a yield of 35% (dry weight basis). Nagai et al. (2000) found that 35.2% collagen was extracted from rhizostomous jellyfish (*Rhopilema asamushi*) by limited pepsin digestion.

CHARACTERISTICS AND PROPERTIES OF COLLAGENS

Collagen from different sources generally has the varying properties, especially the susceptibility to thermal denaturation or cleavage by proteases (Nalinanon et al. 2007, Nalinanon et al. 2010). Fish collagen, comprising lower imino acid content, is less stable than mammalian collagen. This property directly affected the application.

Mammalian Collagen

Bovine skin corium obtained from freshly slaughtered cattle of increasing biological age showed greater resistance to the action of acids, as measured by extractable collagen (Miller et al. 1983). Citrate-soluble content of corium from fetal skin was 30.9%, while that of 3–6-week-old calf was 6.4% and of

Table 20.4. The Conditions for the Extraction of Collagen from Different Sources and Their Yield, Type, and Molecular Compositions

Raw Materials	Pretreatment[a]	Extraction[a]	%Yield (Based on Wet Basis)	Collagen Type	Molecular Compositions	References
Bigeye snapper skin (*Priacanthus tayenus*, T and *Priacanthus macracanthus*, M)	0.1 M NaOH for 6 h, followed by 10% butanol for 18 h	0.5 M acetic acid containing pepsin from tongol tuna stomach extract (TP) or porcine (PP) for 48 h	7.74 (T-PP) 8.73 (T-TP) 7.06 (M-PP) 7.29 (M-TP)	Type I	$(\alpha 1)_2\alpha 2$	Benjakul et al. Figure 20.5. SDS–PAGE patterns of collagen from the skin (S) and bone (B) of bigeye snapper under reducing and nonreducing conditions. M, I, II, III, and V denote high molecular weight protein markers, and collagens type I, II, III, and V, respectively (Kittiphattanabawon et al. 2005).

18-month steer was 3.2%. Similar trends were also noted in neutral salt-soluble (NSC) and pepsin-treated, acid-soluble (PSC) fractions. The greater resistance to degradation in biologically older bovine collagen is thought to be directly related to increased cross-link formation. Gel permeation chromatography, using a newly developed 03BC-Bondagel column, was found to provide a rapid means for separation and determination of molecular size distribution (Miller et al. 1983). Chomarat et al. (1994) compared the effectiveness of two proteolytic enzymes, pepsin and proctase (isolated from *Aspergillus niger*), for the solubilization of collagen from bovine skin. Pepsin- and proctase-solubilized collagens had the similar yields (75% and 76% of total collagen as calculated from hydroxyproline). However, proctase-extracted collagen exhibited a decrease in high-MW components compared with pepsin-extracted collagen (Chomarat et al. 1994).

Collagen was prepared from common minke whale unesu and characterized (Nagai et al. 2008). The yield of collagen was high, about 28.4% (wet weight basis). By SDS–PAGE and TOYOPEARL® CM-650M column chromatography, the collagen was classified as type I collagen. The denaturation temperature of the collagen was 31.5°C, about 6–7°C lower than that of porcine collagen. Attenuated total reflectance-FTIR analysis indicated that ASC from common minke whale unesu held its triple-helical structure well, but the structures of porcine skin collagen and pepsin-solubilized collagen from common minke

whale were changed slightly because of the loss of *N*- and *C*-terminus domains (Nagai et al. 2008).

FISH COLLAGEN

Fish collagen from different sources can have different components. This may affect the properties of those collagens. Generally, fish collagens, from both finfish and shellfish, are classified to be types I and V as a major and minor component, respectively.

Protein Components

Both collagens, from the skin and bone of bigeye snapper (*P. tayenus*), comprised at least two different α-chains, $\alpha1$ and $\alpha2$ (see Fig. 20.5). The $\alpha3$-chain, if present, could not be separated under the electrophoretic conditions employed because $\alpha3$(I) migrates electrophoretically to the same position as $\alpha1$(I) (Kimura and Ohno 1987, Matsui et al. 1991). Collagen of skin and bone from other fish species showed the similarity (Kimura and Ohno 1987, Matsui et al. 1991, Nagai and Suzuki 2000). The electrophoretic patterns of collagens from the skin and bone under nonreducing and reducing conditions were similar, indicating the absence of the disulfide bonds in those collagens. However, peptide maps of collagen from the skin and bone of bigeye snapper, digested by V8 protease and lysyl

endopeptidase, revealed differences between collagens from skin and bone, and both were completely different from those of calfskin collagen (Kittiphattanabawon et al. 2005).

Nalinanon et al. (2008) reported that threadfin bream skin collagen (PSC) obtained with the aid of tuna pepsin showed similar protein patterns compared with those found in ASC. Nevertheless, pepsin from skipjack tuna caused the degradation of α- and β-components. All collagens were classified as type I with large portion of β-chain, consists of two identical α1-chains and one α2-chain. However, proteins with MW greater than 200 kDa were abundant in ASC. Recently, Benjakul et al. (2010) extracted PSCs from the skin of two species of bigeye snapper, *P. tayenus* and *P. macracanthus*, with the aid of tongol tuna (*T. tonggol*) pepsin and porcine pepsin. PSCs from the skin of both species extracted using porcine pepsin had a higher content of β-chain but a lower content of α-chains compared with those extracted using tuna pepsin.

The elution profiles of ASC and PSC from the skin of arabesque greenling on the TOYOPEARL CM-650M column after being denatured by heat treatment in the presence of 2 M urea showed that the primary structure was modified to some degree by albacore tuna pepsin digestion (Nalinanon et al. 2010). β12/β22 dimer of ASC and PSC was the major component, and high-MW component and γ-chain were also detected in the same fractions. It was suggested that some of α2-component might either dimerize covalently into β-component and form β12- or β22-dimer or polymerize into higher MW components. As a result, much lower band intensity of α2-chain was detected on SDS–PAGE and band intensity ratios of α1/α2 more than twofold were observed (Nalinanon et al. 2010). Collagens from alkali–acid extraction and alkali direct extraction of great blue shark skin were composed of α-chains (α1 and α2) (Yoshimura et al. 2000). Based on protein patterns and TOYOPEARL CM-650M column chromatography, ASC and PSC from the skin of brownbanded bamboo shark contained α- and β-chains as their major components and were characterized as type I collagen with the cross-link of α2-chain, which was different from type I collagen from teleost fish species (Kittiphattanabawon et al. 2010a). The similar result was observed in collagens from the skin of blacktip shark (*Carcharhinus limbatus*) (Kittiphattanabawon et al. 2010c). The chromatographic fractions indicated by the numbers were subjected to SDS–PAGE. The fractions of ASC (Fig. 20.6A) and PSC (Fig. 20.6B) were eluted as two major peaks. The α1-chain was found in the first peak (fraction nos. 28–40 and 23–36 for ASC and PSC, respectively), while the α2- and β-chains were found in the second peak (fraction nos. 41–59 and 37–55 for ASC and PSC, respectively). The results revealed that both collagens might be type I collagen, although the band intensity of α1-chain was not twofold higher than that of α2-chain. α2-component might dimerize into the β-component and form β_{12}-dimer (Hwang et al. 2007). As a result, much lower band intensity of α2-chain was detected on SDS–PAGE. Similar results have been reported for collagen type I from other elasmobranches (Hwang et al. 2007, Bae et al. 2008). Hwang et al. (2007) purified PSC from skate skin by differential salt precipitation, followed by phosphocellulose column chromatography. The collagen was purified as major collagen and minor collagen.

The major collagen was defined as type I collagen, contained α1 and α2, with dimerization of α2-chain into β-chain and form β12-dimer. This result was in accordance with other elasmobranch type I collagen obtained from other reports. For the minor collagen, it contained α1 and α2 and was classified as type V collagen.

Fourier Transform Infrared Spectroscopy

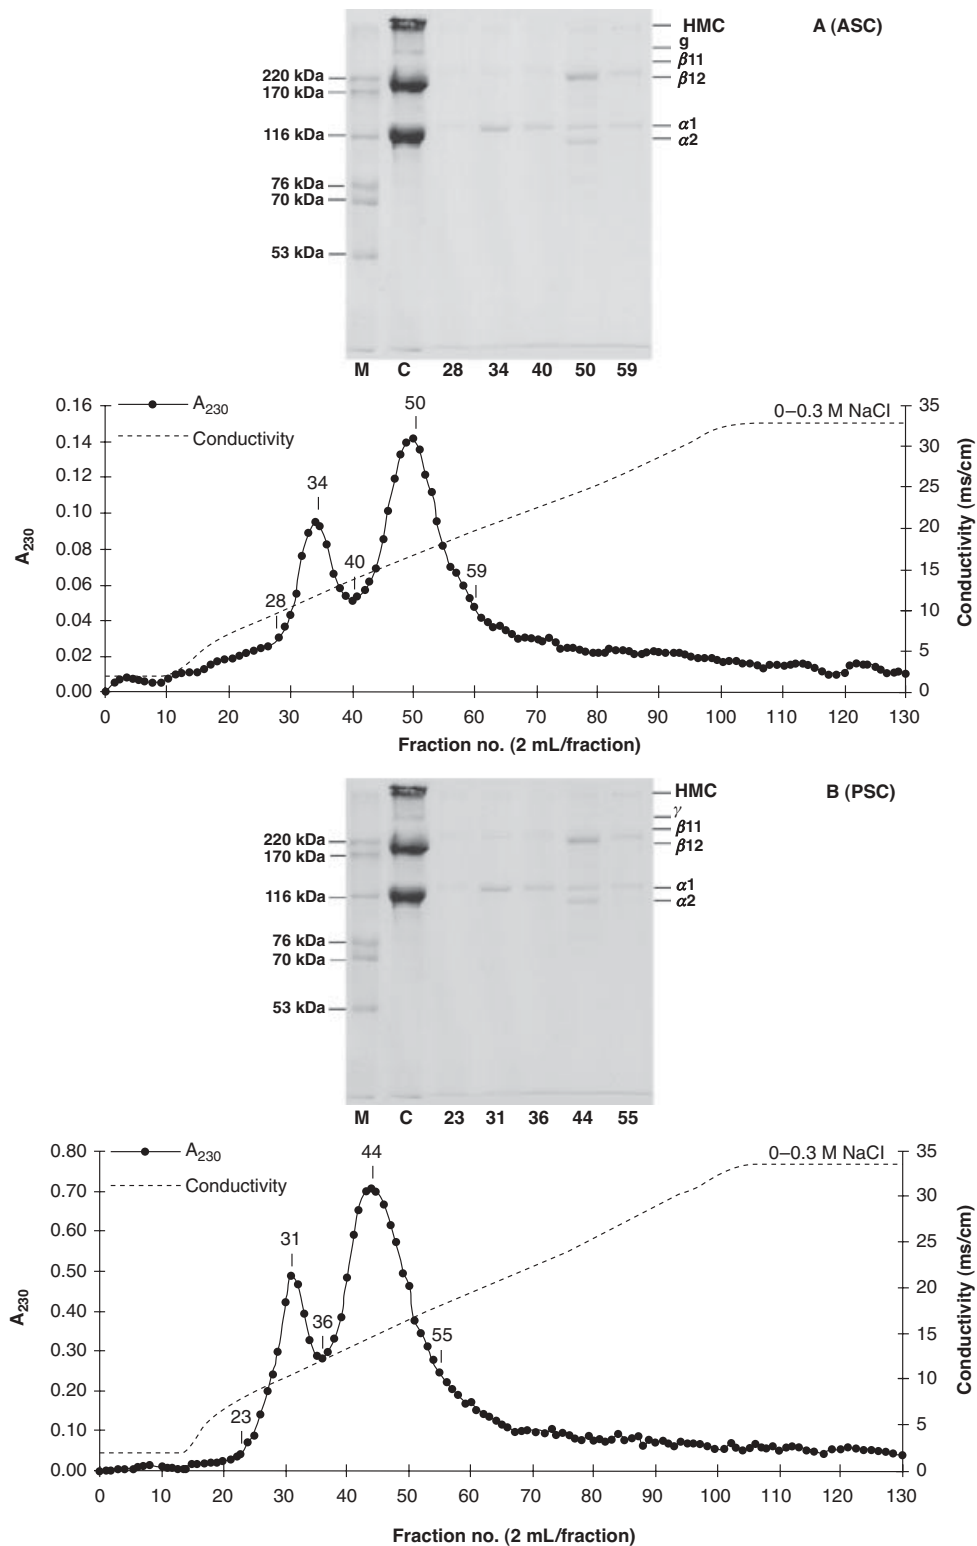
Generally, the collagens from fish skin such as Nile perch (Muyonga et al. 2004), deep-sea redfish (Wang et al. 2007), channel catfish (Liu et al. 2007), yellowfin tuna (Woo et al. 2008), carp (Duan et al. 2009), arabesque greenling (Nalinanon et al. 2010), brownbanded bamboo shark (Kittiphattanabawon et al. 2010a), and blacktip shark (Kittiphattanabawon et al. 2010c) exhibited similar FTIR spectra in which the absorption bands were situated in the amide band region including amides A, B, I, II, and III. A slight difference in FTIR spectra between ASC and PSC from deep-sea redfish (Wang et al. 2007) and arabesque greenling (Nalinanon et al. 2010) has been reported, indicating slight differences in the secondary structure and functional groups of collagens. Amide A band (3400–3440 cm^{-1}) is generally associated with the N–H stretching vibration and shows the existence of hydrogen bonds (Woo et al. 2008, Kittiphattanabawon et al. 2010a). When the NH group of a peptide is involved in a hydrogen bond, the position is shifted to lower frequencies. Amide B band of collagens is observed at 2924–2926 cm^{-1}, which is related to CH_2 asymmetrical stretching vibration (Muyonga et al. 2004). The amide I and II bands of several fish collagens are observed at the wavenumber of 1640–1654 cm^{-1} and 1531–1555 cm^{-1}, respectively (Muyonga et al. 2004, Duan et al. 2009, Nalinanon et al. 2010, Kittiphattanabawon et al. 2010a, 2010c). The amide I band, with characteristic frequencies in the range of 1600–1700 cm^{-1}, is mainly associated with the stretching vibrations of the carbonyl groups (C = O bond) along the polypeptide backbone and is a sensitive marker of polypeptide secondary structure (Payne and Veis 1988, Wang et al. 2007, Kittiphattanabawon et al. 2010c). The shoulder of amide I band appearing at 1637 cm^{-1} could be attributed to the triple helix absorption of collagens (Petibois et al. 2006). Amide II ($\sim$1550 cm^{-1}) is associated with N-H bending coupled with C-N stretching (Muyonga et al. 2004, Woo et al. 2008). Amide III band of collagens is observed at 1234–1238 cm^{-1}, which is related to C-N stretching and N–H in plane bending from amide linkages as well as absorptions arising from wagging vibrations from CH_2 groups from the glycine backbone and proline side chains (Mohd Nasir et al. 2006) involved in triple-helical structure of collagen (Muyonga et al. 2004, Wang et al. 2007, Woo et al. 2008). The triple-helical structure of collagens is also confirmed from the absorption ratio between Amide III and 1450 cm^{-1} bands, which was approximately equal to 1.0 (Plepis et al. 1996, Wang et al. 2007, Kittiphattanabawon et al. 2010a). A slight difference in this ratio between ASC and PSC from deep-sea redfish (Wang et al. 2007) and arabesque greenling (Nalinanon et al. 2010) has been reported. The result suggested that pepsin might affect the triple-helical structure of collagen to some degree. The differences in those ratios and wavenumbers of amide bands between


Figure 20.6. Elution profiles of ASC (A) and PSC (B) from the skin of brownbanded bamboo shark on the TOYOPEARL CM-650M ion-exchange column. The fractions indicated by numbers were examined by SDS–PAGE using 7.5% separating gel and 4% stacking gel. M, C, and HMC denote high-molecular-weight protein markers, collagen, and high-molecular-weight cross-linked components, respectively (Kittiphattanabawon et al. 2010a).

[c]Thermal stability was expressed as T_m.

collagens indicated some differences in the molecular structure. However, the triple-helical structure of PSC from other species, such as brownbanded bamboo shark (Kittiphattanabawon et al. 2010a) and blacktip shark (Kittiphattanabawon et al. 2010c), was not affected by pepsin digestion during collagen extraction. This confirms that pepsin specifically cleaves only at telopeptide regions of tropocollagen.

Thermal Stability

The contents of imino acids (proline and hydroxyproline) are related to thermal stability of collagen. Generally, collagens containing small concentrations of both imino acids denature at lower temperature than do those with the larger concentrations. The maximal transition temperatures (T_m) or denaturation temperatures (T_d) of collagen from different fish are shown in Table 20.5. A high content of imino acid is needed for stabilization of collagen (Xu et al. 2002). The thermal stability of the collagen triple helix is attributed to the hydrogen-bonded networks, mediated by water molecules, which connect the hydroxyl group of hydroxyproline in one strand to the main chain amide carboxyl of another chain (Babu and Ganesh 2001). Therefore, differences in hydroxyproline content might determine the denaturation temperatures of collagens from different species. Collagens derived from fish species living in cold environments have lower contents of hydroxyproline and they exhibit lower thermal stability than those from fish living in warm environment (Muyonga et al. 2004). Therefore, the imino acid content of fish collagens is associated with their thermal stability and correlates with the water temperature of their normal habitat (Foegeding et al. 1996). Norland (1990) reported that collagen from cold-water fish consisted

of imino acid about 16–18%. Muyonga et al. (2004) found that ASC extracted from the skins of young and adult Nile perch contain higher content of imino acids (19.3% and 20.0%, respectively) than that from other fish species. The denaturation temperature for the collagens from the skins of young and adult Nile perch was determined to be 36°C, which was higher than that for most other fish species. The circular dichroism measurement of type I collagens from fish scales of *Pagrus major* and *Oreochromis niloticas* indicated that the denaturation temperatures were dependent on the amount of hydroxyproline rather than proline residues. Raman spectra also indicated that the relative intensities of Raman lines at 879 and 855 cm^{-1} assigned to Hyp and Pro rings were changed due to the contents of the imino acids (Ikoma et al. 2003). Nalinanon et al. (2010) reported that T_m of collagens from the skin of arabesque greenling was 15.4–15.7°C, which was in accordance with that of cold-water fish species such as cod (15°C) (Duan et al. 2009) and deep-sea redfish (16.1°C) (Wang et al. 2007). Denaturation temperatures of skin collagen from several cold- and temperate-water fish including carp (28°C) (Duan et al. 2009), grass carp (28.4°C) (Zhang et al. 2007), ocellate puffer fish (28°C) (Nagai et al. 2002a), tiger puffer fish (28.4°C) (Bae et al. 2008), Japanese seabass (26.5°C), chub mackerel (25.6°C), and bullhead shark (25°C) (Nagai and Suzuki 2000) have been reported. These collagens had much lower denaturation temperature than those of subtropical and tropical fish such as black drum (34.2°C) (Ogawa et al. 2003), sheephead sea bream (34°C) (Ogawa et al. 2003), bigeye snapper (32.5°C) (Nalinanon et al. 2007), brownstripe red snapper (30.5°C) (Jongjareonrak et al. 2005), brownbanded bamboo shark (34.5°C) (Kittiphattanabawon et al. 2010a), and blacktip shark (34.5°C) (Kittiphattanabawon et al. 2010c). The

Table 20.6. Isoelectric Point (pI) of Collagens from Different Sources

Collagens	Sources of Collagen	Sources of Pepsin Used	PI	References
ASC	Arabesque greenling skin	–	6.31	Nalinanon et al. (2010)

	P. macracanthus skin	Tongol tuna	6.44	Benjakul et al. (2010)
	Brownbanded bamboo shark cartilage	Porcine	7.03	Kittiphattanabawon et al. (2010b)
	Blacktip shark cartilage	Porcine	7.26	Kittiphattanabawon et al. (2010b)

differences in denaturation temperature of collagen from different sources might be governed by different contents of imino acids (proline and hydroxyproline) (Jongjareonrak et al. 2005, Zhang et al. 2007, Kittiphattanabawon et al. 2010a). The thermal stability of collagen is associated with the restriction of the secondary structure of the polypeptide chain governed by the pyrrolidine rings of proline and hydroxyproline and partially by the hydrogen bonding through the hydroxyl group of hydroxyproline (Benjakul et al. 2010).

Zeta (ζ) Potential

Charge of proteins plays a role in properties, especially solubility as well as interaction with other molecules via ionic interaction. Collagen from different fish possesses the zero net charge at pH range of 6.21 to 7.26 (Table 20.6). Generally, the pI of collagen is determined by amino acid composition. The pH where the ζ-potential is zero corresponds to the pI of the protein (Ma et al. 2009), in which a net electrical charge of zero at the surface is obtained. The collagens had a net positive or negative charge when pH values are below and above their pI, respectively (Nalinanon et al. 2010, Kittiphattanabawon et al. 2010a, b, c). At pI of proteins, hydrophobic–hydrophobic interaction increased, thereby promoting the precipitation and aggregation of protein molecules (Jongjareonrak et al. 2005). Nalinanon et al. (2010) determined the ζ-potential of ASC and PSC from arabesque greenling (*Pleurogrammus azonus*) at different pHs. Generally, ζ-potential profiles of both collagens were similar within pH range tested (Fig. 20.7). The similarity in ζ-potential profiles of ASC and PSC indicated that partial removal of telopeptides
Figure 20.7. Zeta (ζ) potential of ASC and PSC from the skin of arabesque greenling at different pHs. Bars represent the standard deviation from triplicate determinations (Nalinanon et al. 2010).

in PSC by the albacore tuna pepsin did not significantly alter surface charge of collagen (Nalinanon et al. 2010). However, slight differences in ζ-potential profiles of ASC and PSC from shark skins were observed when porcine pepsin was used as extraction aid. The difference in pI and the rate of changes in ζ-potential between ASC and PSC from shark skins might be caused by the different amino acids mediated by partial removal of telopeptides by pepsin used (Kittiphattanabawon et al. 2010a, 2010c). It was noticed that PSCs from different sources showed different pIs. Benjakul et al. (2010) reported that PSC of the skin of *P. tayenus* showed a higher pI than those from the skin of *P. macracanthus*. For the same skin, PSCs prepared using porcine pepsin possessed a lower pI than those prepared using tongol tuna pepsin. Owing to the similar amino acid composition of all PSCs, the differences in net surface charge at different pHs were most likely governed by the different unfolding or exposure of charged amino acids, in which protonation or deprotonation could take place to different degrees (Benjakul et al. 2010). Thus, the different pepsins may cleave the telopeptide region at different sites, leading to differences in the ease of conformational changes at different pHs and to different charges at the surface (Benjakul et al. 2010, Kittiphattanabawon et al. 2010b). The pI of ASC and PSC of arabesque greenling was estimated to be 6.31 and 6.38, respectively. Both collagens had pI in a slight acidic pH. This might be due to higher content of acidic amino acids, aspartic acid, and glutamic acid compared with basic amino acids, including histidine, lysine, and arginine (Nalinanon et al. 2010). The pI of collagens from the skin of brownbanded bamboo shark and blacktip shark was reported in the range of 6.21–7.02 (Kittiphattanabawon et al. 2010a, 2010c). The pI of ASC and PSC from the cartilage of brownbanded bamboo shark and blacktip shark were estimated to be 6.53, 7.03, 6.96, and 7.26, respectively. The difference in pI between both shark cartilages might be caused by the variation in their amino acid compositions (Kittiphattanabawon et al. 2010b). Proteins arise from different genes may have a variable number of amino acids with charged side chains, resulting in different surface charge and a variety of pI values (Bonner 2007).

INVERTEBRATE COLLAGEN

Collagens with different types and contents have been found in invertebrates. The presence of homotrimetic collagen molecules $(\alpha1)_3$ has been demonstrated in the muscle of abalone *Haliotis discus* and top shell *Turbo cornutus* (Yoshinaka and Mizuta 1999). Kimura and Matsuura (1974) reported that collagen extracted by limited digestion with pepsin from foot muscle of abalone consisted of $\alpha3$-chain, while collagens from the skins of octopus and squid, and the subcuticular membranes of swimming crab and spiny lobster had $(\alpha1)_2\alpha2$, commonly found in various vertebrate collagens. The squid and lobster collagens contained the greater amount of glycosylated hydroxylysines (mainly glucosylgalactosylhydroxylysine) than most vertebrate collagens (Kimura and Matsuura 1974). On the other hand, bivalves have been shown to possess $(\alpha1)_2\alpha2$ heterotrimers, which have similar compositional features to vertebrate type I collagen. The byssus threads of sea mussel (*Mytilus edulis*) and

the adductor muscles of pearl oyster (*Pinctada fucata*) contained heterotrimer collagen $(\alpha1)_2\alpha2$ (Yoshinaka and Mizuta 1999). Xuan Ri et al. (2007) reported that PSC from scallop (*Patinopecten yessoensis*) mantle consisted of two different collagen molecules, with different profiles in molecules, amino acids, and peptide maps, and had different uronic acid contents and gel-forming abilities.

Collagen in the mantle muscle of common squid *Todarodes pacificus* consisted of two genetically distinct types of PSC (Yoshinaka and Mizuta 1999). The major collagen, named type SQ-I collagen, is insoluble in 0.5 M acetic acid containing 0.45 M NaCl, and has a similar amino acid composition to those of vertebrate type I collagen. Type SQ-I collagen is the major collagen in the cranial cartilage and skin of common squid *T. pacificus* and in the skin and arm muscle of octopus *Octopus vulgaris*. In addition, similar collagens have been isolated from the sucker of cuttlefish and octopus. The minor collagen, called type SQ-II, is very soluble in 0.5 M acetic acid containing 0.45 M NaCl. Type SQ-II collagen has some compositional characteristics similar to vertebrate type V collagen, showing a low level of alanine and high level of hydroxylysine. Both type SQ-I and SQ-II collagens are heterotrimers, of which the subunit compositions are represented as $[\alpha1(SQ-I)]_2\alpha2(SQ-I)$ and $[\alpha1(SQ-II)]_2\alpha2(SQ-II)$, respectively (Yoshinaka and Mizuta 1999). Octopus *Callistoctopus arakawai* arm consisted of ASC and PSC at levels of 10.4% and 62.9%, respectively. PSC had a chain composition of $\alpha1\alpha2\alpha3$ heterotrimer, while ASC showed only a single α-chain, $\alpha1$. The denaturation temperature of those collagens was lower than that of porcine collagen (Nagai et al. 2002b). Nagai and Suzuki (2002) found that the collagen extracted from the outer skin of the paper nautilus was hardly solubilized in 0.5 M acetic acid. The insoluble matter was easily digested by 10% pepsin (w/v), and a large amount of collagen (PSC) was obtained with about a 50% yield. PSC had a chain composition of $\alpha1$ $\alpha2$ $\alpha3$ heterotrimer similar to *C. arakawai* arm collagen. PSC from skin of cuttlefish (*S. lycidas*) had a chain composition of $(\alpha1)_2\alpha2$ heterotrimer, which was similar to Japanese common squid PSC. The denaturation temperature of this collagen was 27°C, that is about 10°C lower than that of porcine collagen.

The primary structure of PSC from rhizostomous jellyfish was very similar to that of PSC from edible jellyfish mesogloea, but it was different from those of the collagen from edible jellyfish exumbrella and the ASC from its mesogloea. The rhizostomous jellyfish mesogloea collagen had a denaturation temperature (T_d) of 28.8°C. This collagen contained a large amount of a fourth subunit, designated as $\alpha4$. This collagen may have the chain composition of an $\alpha1\alpha2\alpha3\alpha4$ heterotetramer. Mizuta et al. (1998) reported that collagen from muscle of Antarctic krill, *Euphausa superba*, referred to as $\alpha1(Kr)$ component, constituted more than 80% of the total pepsin-soluble collagen and showed typical compositional feature of crustacean major collagens, with low alanine and high hydroxylysine contents. The $\alpha1(Kr)$ component was mainly distributed in relatively thick connective tissues, epimysium and perimysium. $\alpha1(Kr)$ component may functionally correspond to the major α-component of collagen in decapods, $\alpha1(AR-I)$ (AR-I : Arthropod-type I), and comprise a major homotrimeric collagen molecule, $[\alpha1(AR-I)_3]$.

FACTOR AFFECTING COLLAGEN PROPERTIES

Some factors have been known to influence the collagen properties. pH and salt concentration were reported to affect water-binding capacity, viscosity, and emulsifying properties of collagen from fish muscle and skin connective tissues (Montero et al. 1991). Jongjareonrak et al. (2005) reported that maximum solubility in 0.5 M acetic acid of collagen from brownstripe red snapper (*Lutjanus vitta*) was observed at pH 3 and 4 for ASC and PSC, respectively. A sharp decrease in solubility was observed in the presence of NaCl above 2% and 3% (w/v) for ASC and PSC, respectively. Collagens from the skin and bone of bigeye snapper (*P. tayenus*) had the highest solubility at pH 2 and 5, respectively. No changes in solubility were observed in the presence of NaCl up to 3% (w/v). However, a sharp decrease in solubility was found with NaCl above 3% (w/v) (Kittiphattanabawon et al. 2005). Where pH was between 2 and 4, the solubility and water binding capacity of trout (*Salmo irideus* Gibb) collagen were highest, but in the addition of NaCl, functionality was reduced (Montero et al. 1991). Montero et al. (1999) also reported that solubility, apparent viscosity, and water-binding capacity of collagenous material from hake and trout showed the maximum values at pH levels between 2 and 4 and at concentrations less than 0.25 M NaCl. Furthermore, emulsifying capacity decreased as the NaCl concentration increased and was highest at pH levels between 1 and 3 (Montero et al. 1991).

Collagen properties are also affected by processing parameters such as freezing, heating, and so on. Montero et al. (1995) compared four stabilizing methods: (1) freezing, (2) freeze-drying, (3) partial solubilization with 0.05 M acetic acid then freezing, and (4) partial solubilization with 0.05 M acetic acid then freeze-drying on the functional properties of collagen from plaice skin. Only freeze-drying caused reduction in solubility and emulsifying capacity. Viscosity was greatest when samples were presolubilized. Emulsifying capacity was not changed when samples were frozen and decreased when they were either freeze-dried or presolubilized. Optimum water-holding capacity was observed in samples, which were previously solubilized. During the storage of fish on ice, a progressive change in solubility of muscle collagen was found. For insoluble collagen, significantly lower values were detected at day 15 compared with day 0. A little increase in ASC was found, while no changes were seen in PSC during storage (Eckhoff et al. 1998). Therefore, some cleavage of intermolecular cross-links seems to occur during storage on ice (Eckhoff et al. 1998).

APPLICATIONS OF COLLAGEN

Food Applications

The collagen protein can be refined so that it can be used in processed meat products to improve protein functionality through the immobilization of free water, increasing the stability of the finished product (Prabhu et al. 2004). Kenney et al. (1992) used pork collagen as an inexpensive adjunct to increase cooking yields and tensile strength in restructured beef. In addition, the use of 10% raw and preheated pork collagen reduced (*P* < 0.05) product initial cohesiveness and juiciness and tended (*P* < 0.09) to reduce beefiness. Utilization of pork collagen in boneless cured pork that incorporates pale, soft, and exudative (PSE) meat increases water-holding capacity and has the potential to improve protein functionality characteristics of the product (Schilling et al. 2003). Effects of pork collagen in emulsified and whole muscle products have also been evaluated. Prabhu et al. (2004) found that incorporation of pork collagen at 1% and above significantly (*P* < 0.05) increased cooked and chilled yields in frankfurters but did not have any effect in hams. Purge was significantly (*P* < 0.05) reduced in both frankfurters and hams after 4 weeks of storage. Sensory difference testing showed no significant difference up to 2% usage level of pork collagen in both frankfurters and hams (*P* > 0.05). The use of pork collagen as a binder and extender in emulsion sausages and hams provides for the absorption and binding of moisture, so that during thermal processing, cook losses are minimized. (Prabhu et al. 2004). Effects of raw material and the inclusion of chicken collagen on the protein functionality of chunked and formed chicken breast manufactured from 100% PSE like and 100% normal broiler breast with either 0% or 1.5% collagen were determined (Schilling et al. 2005). Inclusion of collagen was effective in decreasing cooking loss and increasing protein–protein bind. PSE like with no collagen had lower (*P* < 0.05) protein–protein bind than normal meat with collagen. Schilling et al. (2004) also found that inclusion of turkey collagen improved the texture of turkey breast deli products through increasing the protein's ability to bind with each other in pale meat and was effective in decreasing cooking and purge loss in both pale and normal samples. These results revealed that addition of collagens is effective in increasing water-holding capacity and has the potential to improve quality characteristics of products made from either pale or normal raw material.

Biomedical Applications

The primary reason for the usefulness of collagen in biomedical application is that collagen can form fibers with extra strength and stability through its self-aggregation and cross-linking (Lee et al. 2001). Out of the ten collagen types that have been characterized, types I, III, and V are the most desirable for biomedical applications because of their high biocompatibility and low immunogenicity (Antiszko et al. 1996). Uses of collagen as surgical suture, hemostatic agents, and tissue engineering including basic matrices for cell systems and replacement/substitutes for artificial blood vessels and valves were reported (Lee et al. 2001). As a commercial medical product, collagen can be part of natural, stabilized tissue that is used in the device, for example, as in a bioprosthetic heart valve, or it can be fabricated as a reconstituted, purified product from animal sources, for example, as in wound dressings (Ramshaw et al. 2009). Polymers of natural origin that function as regeneration templates have so far been synthesized as graft copolymers of collagen and chondroitin 6-sulfate, a glycosaminoglycan. Certain collagen-graft glycosaminoglycans can induce synthesis of dermis within a wound bed in guinea pigs in which the epidermis and the

complete dermis have been removed by surgical excision (Meena et al. 1999). Wisser and Steffes (2003) described the successful wound management of a 19-year-old patient with 63% of the body surface burnt covered with Integra[R], consists of a modified bovine collagen matrix and a silastic membrane facing toward the body surface. After 1 year of surgical development, a common feature of wound areas treated with Integra showed the good sliding characteristics of the skin on its support and the lack of scar lines. Taguchi et al. (2004) developed a novel tissue adhesive, consisting of type I collagen from pig skin and cross-linking by citric acid derivative. This adhesive is biodegraded under the skin of mice within 7 days after subcutaneous injection. Synthetic materials in the form of dressings are used primarily for treatment of superficial wounds to prevent moisture and heat loss from the skin as well as to prevent bacterial infiltration from the environment (Meena et al. 1999). Antiszko et al. (1996) developed collagen membranes as carriers of antiseptics. Microdressings prepared with collagen membranes containing povidone-iodine or chlorhexidine glycerin solution and packed into envelopes made of laminated aluminum foil were stable for 8 weeks concerning their antibacterial activity. After implantation beneath mouse skin, the dressings did not cause inflammation. Such dressings may be useful in a treatment of ulcers, superficial burns, and chronic granulated wounds (Antiszko et al. 1996).

Advantages of collagen for biomedical application include (Meena et al. 1999) (i) abundant sources of highly purified (medical grade) collagen, (ii) the ability to be reconstituted into high strength forms useful in surgery, (iii) the wealth of research literature on the characterization of collagen, (iv) improved processing techniques, (v) introduction of several commercial collagen products, and (vi) recent advances in the use of collagen as a delivery system.

Pharmaceutical Applications

Bovine collagen was approved by the Food and Drug Administration in 1982, and since that time, it has remained as a primary filler of choice for soft-tissue augmentation of dermal defects (Matarasso 2006). The advent of human-derived collagen from fibroblast cultures further increased the popularity of injectable products. Cultured autologous collagen and several other formulations of collagen have been undergoing clinical trials or are available outside the United States (Matarasso 2006). These advances in collagen technology may deliver products that are more persistent in duration and comfortable to administer than materials that are presently in use. It is widely known that the digestion of collagen proteins or hydrolysates in vivo will generate peptides that may be useful for organic biosynthetic processes (Cúneo et al. 2010). Thus, the consumption of collagen-rich foods might be beneficial for bone health. Several functional properties of enzymatic collagen hydrolysates have been investigated in osteoarthritis and suggest a beneficial stimulating effect with an increased synthesis of extracellular matrix macromolecules produced by chondrocytes (Bello and Oesser 2006, Cúneo et al. 2010). Wu et al. (2004) postulated that oral administered collagen peptide may provide beneficial effects on bone

metabolism in rat, especially in the calcium-deficient condition, without obvious undesirable effects. In a randomized, double-blind, placebo-controlled trial with osteoporotic women, Adam et al. (1996) investigated the use of a diet rich in collagen hydrolysate (10 g/day) and observed that calcitonin associated with this type of diet had a greater effect in inhibiting bone collagen breakdown than calcitonin alone, as determined by a decrease in urinary levels of pyridinoline cross-links. Bello and Oesser (2006) postulated that collagen hydrolysate ingestion stimulates a statistically significant increase in synthesis of extracellular matrix macromolecules by chondrocytes compared with untreated controls. These findings suggest mechanisms that might help patients affected by joint disorders such as osteoarthritis. A growing body of evidence provides a rationale for the use of collagen hydrolysate for patients with osteoarthritis (Bello and Oesser 2006). The cell biological properties of collagen, gelatin, and collagen hydrolysate ($<15,000$ Da) were studied using murine keratinocytes (Li et al. 2005). Keratinocyte culture experiments demonstrated that only collagen had significant effects on cell attachment and proliferation, but the results of cells cultured on gelatin and collagen hydrolysate showed that the rates of adhesion and proliferation were similar to those of cells cultured on plastic as a control. It is concluded that collagen has better physiological effects than those of gelatin and collagen hydrolysate as skin-care cosmetic materials (Li et al. 2005).

In addition, collagen has served as an excellent carrier for drug delivery systems. Collagen can be extracted into an aqueous solution and molded into various forms of delivery systems. The main applications of collagen as drug delivery systems are collagen shield in ophthalmology, sponges for burns/wounds, minipellets and tablets for protein delivery, gel formulation in combination with liposomes for sustained drug delivery, controlling material for transdermal delivery, and nanoparticles for gene delivery (Lee et al. 2001). Atelocollagen, which is produced by elimination of the telopeptide moieties using pepsin, has demonstrated its potential as a drug carrier, especially for gene delivery (Kohmura et al. 1999, Ochiya et al. 1999, Lee et al. 2001). Ho et al. (1997) demonstrated that gel formulation prepared by gelling the vehicle mixture of citric acid solution, ethanol, and propylene glycol with 1% (w/w) of telopeptide-poor collagen (atelocollagen) sample was suitable for transdermal delivery. Takaoka et al. (1991) reported that bovine skin collagens prepared by use of conventional methods (acid-solubilized collagen, or collagen-digested once with pepsin) were also assessed as carriers for bone morphogenetic protein (BMP) in mice, but were found to be inferior in terms of consistency of bone formation and amount of induced bone mass. The results suggest that telopeptide-depleted collagen (atelocollagen) permitted a gradual release of purified BMP for induction of bone, with minimal immunogenic interference. Consequently, this collagen carrier represents an important development for future clinical application of BMP (Takaoka et al. 1991). Ochiya et al. (1999) described a new gene transfer method that allows prolonged release and expression of plasmid DNA in vivo in normal adult animals through the use of atelocollagen, a biocompatible polymer, as the carrier. Plasmid DNA was carried in the atelocollagen, resulting in a minipellet of cylindrical shape (0.6 mm in diameter

and 10 mm in length) that contained 50 μg of plasmid DNA and human HST-1/FGF-4 cDNA. The minipellet was able to carry the bioactive macromolecules even when as much as 50% (w/w) of the atelocollagen was replaced by pharmaceutical ingredients and/or bioactive macromolecules. This new technique of controlled gene transfer using atelocollagen and allowing prolonged systemic circulation of target products will facilitate a more effective and long-term use of naked plasmid vectors for somatic gene therapy.

Fish Gelatin

Soottawat Benjakul, Phanat Kittiphattanabawon, and Joe M. Regenstein

Abstract: Fish gelatin, partially hydrolyzed or denatured collagen, has received attention as the alternative of mammalian and avian gelatin. It can be extracted from the by-products rich in collagen such as fish skin, bone, scale, or the skin of some invertebrate, and so on. Composition and properties of fish gelatin can be governed by the sources of raw materials. Processing parameters such as pretreatment, extraction temperature, bleaching, drying, and so
on influence the chemical and functional properties of gelatin. Generally, fish gelatin exhibited lower functional properties than those from land animals, thereby limiting the applications of fish gelatin. Several approaches have been therefore developed to improve the properties of fish gelatin via modification using chemical or enzymatic processes. Therefore, fish gelatin can be applied more widely in several industries.

INTRODUCTION

Gelatin is biopolymer obtained from partial denaturation of collagen. It has a wide range of applications in food and nonfood (photographic, cosmetic, and pharmaceutical) industries (Regenstein and Zhou 2007a). Generally, gelatin is obtained from mammals, especially pig and cow skins and bones. Recently, outbreaks of mad cow disease (bovine spongiform encephalopathy, BSE) have caused anxiety in customers. Additionally, the gelatin obtained from pigskin and pig bone cannot be used in Kosher and Halal foods due to religious constraints. Furthermore, an increasing attention to health issues by consumers has also resulted in a high demand of fish gelatin (Kittiphattanabawon et al. 2010). As a consequence, the alternative sources for gelatin production have been intensively increased, especially skin, bone, and scale from seafood processing by-products due to their abundance and low cost. However, fish gelatins have limited application, mainly owing to the lower gel strength and lower gel stability, compared with those from their mammalian counterparts (Leuenberger 1991). This chapter covers the literature reviews of gelatin, particularly fish gelatin, regarding their production, functional properties, and improvement of their functional properties as well as applications.

Gelatin is one of the commonly used food ingredients, obtained by the thermal denaturation of collagen (Bailey and Light 1989). The process involves the disruption of noncovalent

bonds and is partially reversible in agreement with the gelling properties of gelatin (Bigi et al. 1998). Gelatin has been widely applied in the food industry as ingredients to improve the elasticity, consistency, and stability of foods. It can be used for medical and pharmaceutical purposes such as encapsulation, production of hard and soft capsules, wound dressing, adsorbent pads, and edible film formation. Furthermore, it can be applied for biomaterial-based packaging and photographic industries (Jongjareonrak et al. 2006c).

PRODUCTION OF GELATIN

Production of gelatin can be divided into three main steps, (1) pretreatment, (2) extraction, and (3) drying (Fig. 21.1). All processes used for gelatin extraction have direct impact on the yield and properties of gelatin obtained. The process has been optimized for different sources of raw materials (Cho et al. 2004, Zhou and Regenstein 2004, Cho et al. 2005, Yang et al. 2007).

PRETREATMENT OF RAW MATERIAL

Removal of Noncollagenous Protein

Prior to gelatin extraction from raw material, the pretreatment is practically implemented to increase purity of gelatin extracted. Alkaline solution has been used to remove considerable amounts of noncollagenous materials (Johns and Courts 1977, Zhou and Regenstein 2005) and break some interchain cross-links. Also, the process is able to inactivate proteases involved in degradation of collagen (Regenstein and Zhou 2007b). During alkaline pretreatment, the type of alkali does not make a significant dif-

ference, but the concentration of alkali is critical (Zhou and Regenstein 2005). Yoshimura et al. (2000) reported that alkali attacks predominantly the telopeptide region of the collagen molecule during pretreatment. Thus, some collagen can be solubilized by an alkali solution. Long time and high concentration of alkaline pretreatment decreased the yield of gelatin from skin of channel catfish (Yang et al. 2007). The concentration of alkali, time, and temperature used for pretreatment varied with raw materials (Table 21.1).

Table 21.1. Pretreatment Conditions for the Extraction of Gelatin from Different Fishes

| Raw Materials | Alkaline Type/Concentration | Conditions | | | References |
		Temperature (°C)	Time (min)	Alkaline Changing (times)	
Brownbanded bamboo shark and blacktip shark	0.1 M NaOH	15–20	40	3	Kittiphattanabawon et al. (2010)

[a]NM: not mentioned.

Removal of Fat

Raw material with high fat content can be associated with the negative effect on gelatin. Soaps may be formed during treatment with alkali prior to gelatin extraction. This soap can contaminate the resulting gelatin. Nevertheless, fat removal process was not included in the pretreatment process for gelatin extraction from some fish skin with low fat content (Gudmundsson and Hafsteinsson 1997, Gómez-Guillén et al. 2003, Zhou and Regenstein 2004Arnesen and Gildberg 2007, Cheow et al. 2007, Yang et al. 2007, Aewsiri et al. 2008, Nalinanon et al. 2008, Rahman et al. 2008). A simple defatting can be achieved by hot water (Waldner 1977). Muyonga et al. (2004) removed fat in bone of Nile perch (*Lates niloticus*) by tumbling in warm water (35°C).

Removal of Minerals

Demineralization of the raw material, especially bone or scale, aims to remove the calcium and other inorganic substances to facilitate the extraction of collagenous component (Waldner 1977). The inorganic substances in raw material can be removed by treatment with dilute hydrochloric acid solution, whereby the calcium phosphate is dissolved as acid phosphates (Waldner 1977). The fresh bone is commonly treated with hydrochloric acid solution, in which almost all minerals are completely removed. Depending on the nature of the material, temperature, and acid concentration, the demineralization time can be varied. The acid concentration used is in the range 2–6% HCl (Waldner 1977). Acid hydrolysis of the protein should be minimized during demineralization. High temperature should also be avoided since it can enhance the hydrolysis of protein. Bone from Nile perch (*Lates niloticus*) was demineralized with 3% HCl at room temperature prior to extraction using warm water (60°C) (Muyonga et al. 2004). Demineralization of tuna fin (*Katsuwonus pelamis*) was carried out at room temperature using 0.6 N HCl (Aewsiri et al. 2008).

Swelling of Pretreated Raw Materials

Prior to gelatin extraction, pretreatment is generally required to enhance the extraction efficiency. Swelling is important because it can favor protein unfolding by disruption of noncovalent bonding and predispose the collagen to subsequent extraction and solubilization (Stainby 1987). Pretreatments can be classified into two processes and are selectively used on the basis of the raw materials.

Acid Process   Acid hydrolysis is a milder treatment that effectively solubilizes collagens of animals slaughtered at a young age such as pigs (Foegeding et al. 1996). The pretreatment is aimed to convert the collagen into a form suitable for extraction. The covalent cross-links in the collagen must be disrupted to enable the release of free α-chains during the extraction (Johnston-Banks 1990). The process is able to remove other organic substances. Sulfuric and hydrochloric acids are used, often with the addition of phosphoric acid to retard color development (Johnston-Banks

1990). Additionally, the acid pretreatment can partially inactivate endogenous proteases involved in degradation. As a result, the enzymatic breakage of intrachain peptide bonds of collagen during extraction can be lowered (Zhou and Regenstein 2005). Nalinanon et al. (2008) reported that gelatin extraction from bigeye snapper skin using a pepsin-aided process in combination with a protease inhibitor showed the higher bloom strength than the gelatin extracted by the conventional process, which had a substantial degradation of gelatin components.

Moreover, type of acid and concentration affected the yield and properties of gelatin. The concentration of H^+ used in processing of gelatin from cod skins affected yield and quality of resulting gelatin (Gudmundsson and Hafsteinsson 1997). Megrim skin was treated with 0.05 M acetic and 0.05 M propionic acid prior to gelatin extraction using distilled water at 45°C for 30 minutes. The gelatin obtained had the highest elastic modulus, viscous modulus, melting temperature, and gel strength. On the other hand, gelatin obtained from skin swollen with citric acid exhibited the lowest turbidity of gelatin solution, whereas propionic acid led to the most turbid gelatin solution (Gómez-Guillén and Montero 2001). Gimenez et al. (2005) reported that use of lactic acid (25 mM) could be an excellent substitute for acetic acid for the skin swelling process. The gelatin so obtained showed similar properties to that prepared by using 50 mM acetic acid without the negative organoleptic properties. Gelatin obtained from the acid process is known as type A gelatin.

Alkaline Process   Type B gelatins are generally produced by alkali hydrolysis of bovine materials. This process results in deamidation as well as degradation, leading to the lowered chain length (Foegeding et al. 1996). Alkaline pretreatments are normally applied to bovine hide and ossein. Lime is most commonly used for this purpose; it is relatively mild and does not cause significant damage to the raw material by excessive hydrolysis. However, 8 weeks or more are required for complete treatment. Lime at concentrations of up to 3% is used in conjunction with small amounts of calcium chloride or caustic soda. Alkaline process using caustic soda takes 10–14 days for pretreatment (Johnston-Bank 1983). Gelatin obtained from the alkaline process is known as type B gelatin.

Cho et al. (2004) optimized the extraction condition for production of gelatin from shark cartilage using response surface methodology. Gelatin production has two important steps, (1) alkali treatment and (2) hot-water extraction. The alkali treatment removes noncollagenous protein. Hot-water extraction causes thermal hydrolysis, leading to the solubilization of gelatin. The predicted maximum yields of 79.9% for gelatin production were obtained when alkali treatment using 1.6 N NaOH for 3.16 days and hot-water extraction at 65°C for 3.4 hours were implemented.

Acid Process in Conjunction with Pepsin   Traditionally, alkaline process has been used for gelatin production from raw material with high degree of cross-linking. These harsh conditions result in random hydrolysis of peptide bonds and decomposition of some amino acids, leading to a product of variable quality with a broad molecular weight distribution (Slade and

Levine 1987, Galea et al. 2000). Generally, gelatin quality is determined by the length of collagen chains: longer chains produce higher quality gelatin (Tomka 1982, Galea et al. 2000). To obtain the high-quality gelatin, acid process should be used for gelatin production since this process disrupts acid-labile collagen cross-links with negligible peptide bond hydrolysis and less amino acids are destroyed (Slade and Levine 1987, Galea et al. 2000). However, raw materials with high amount of molecular cross-links result in the lower extraction yield (Galea et al. 2000). To increase the extraction yield, some proteases capable of solubilizing the collagen or cleaving the cross-links have been applied during acid process. In general, triple-helical domain of collagen is relatively resistant to proteolytic attack, while the terminal telopeptide regions, which contain inter- and intramolecular cross-links, are readily cleaved (Galea et al. 2000). Chomarat et al. (1994) prepared bovine skin gelatin using pepsin or proctase (isolated from *Aspergillus niger*) to solublize the collagen prior to extraction at 90°C. Both enzymes solubilized collagen with a yield of 75–76% as calculated from hydroxyproline content. After heating, collagen was converted to gelatin with yields of 32% and 39% when pepsin and proctase were used as the extraction aid, respectively. Nalinanon et al. (2008) reported that the extraction yield of gelatin from bigeye snapper skin treated with pepsin during swelling process was approximately two fold higher than that of gelatin from skin without pepsin treatment.

EXTRACTION OF GELATIN

When the heat is applied, collagen fibrils shrink to less than one-third of their original length at a critical temperature known as the shrinkage temperature (Foegeding et al. 1996). This shrinkage involves a disassembly of fibers and a collapse of the triple-helical arrangement of polypeptide subunits in the collagen molecule. During the collagen to gelatin transition, many non-covalent bonds are broken along with some covalent inter- and intramolecular bonds (Schiff base and aldo-condensation bonds) and a few peptide bonds are cleaved. Heat applied at temperature higher than transition temperature (T_{max}) is able to disrupt the bonds, mainly H-bond, which stabilizes collagen structure (Fig. 21.2). This results in conversion of the helical collagen structure to a more amorphous form known as gelatin. Nevertheless, when the collagen molecule is completely destructured, glue is produced instead of gelatin (Foegeding et al. 1996). The conversion of collagen to gelatin yields molecules of varying mass, depending on the temperatures used, indigenous proteinases, and so on. Therefore, gelatin is a mixture of fractions varying in molecular weight from 15 to 400 kDa (Gelatin Manufacturers Institute of America 1993).

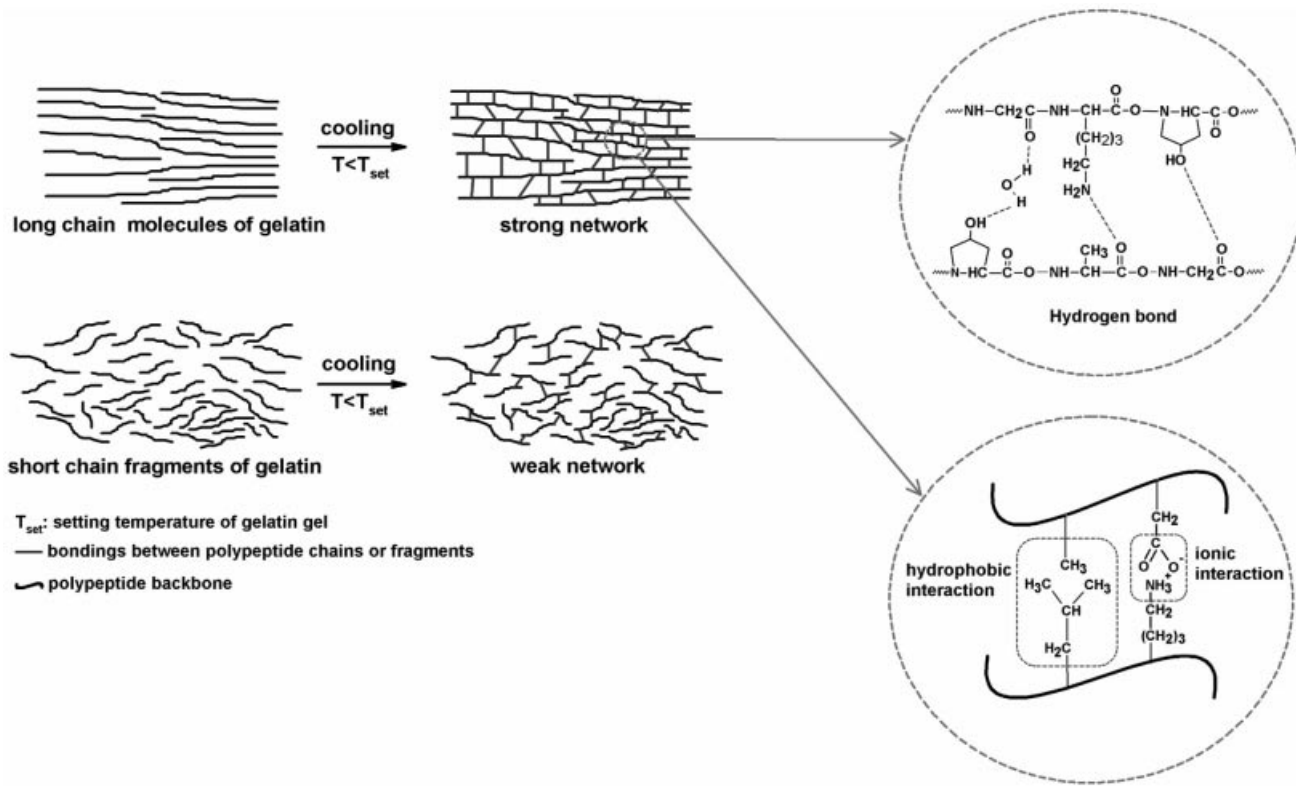
The maximum yield together with the desirable physical properties is the main objective for the processor. The pH of extraction can be selected either for the maximum extraction rate


Figure 21.2. Gelatin network associated with hydrogen bond, hydrophobic interaction, and ionic interaction.

(low pH) or for the maximum physical properties (neutral pH) (Johnston-Banks 1990). Basically, more efficient pretreatment conditions allow the manufacturer to use lower extraction temperatures, and still obtain gelatins with high bloom strength (Johnston-Banks 1990). Shorter time is generally associated with higher extraction temperatures if neutral pH levels are chosen. However, lower gel strength is obtained (Johnston-Banks 1990). Muyonga et al. (2004) reported that Nile perch skin extracted at higher temperature yielded lower gel strength, melting point, setting temperature, and longer setting time. Yang et al. (2007) also reported that gelatin from channel catfish skin showed lower gel strength as extraction temperature was increased from 60°C to 75°C. Additionally, gelatin extracted from the skin of brownbanded bamboo shark and blacktip shark using higher temperature had decreasing band intensity of major components (α-, β- and γ-chains) as well as increasing low-molecular weight components. Such changes correlated well with lowered bloom strength. Shorter chain fragments of gelatin could not form the junction zone, in which the strong network could be developed (Kittiphattanabawon et al. 2010) (Fig. 21.2).

Drying

After extraction, the gelatins are filtered to remove suspended or insoluble matters including fat, unextracted collagen fibers, and other residues. Diatomaceous earth or activated carbon can be used to make gelatin solution clear. The final stage is evaporation, sterilization, and drying. These are performed as quickly as possible to minimize loss of properties (Johnston-Banks 1990). Kwak et al. (2009) extracted gelatin from shark cartilage using three drying methods, (1) freeze drying, (2) hot-air drying, and (3) spray drying. Freeze-dried gelatin showed the highest gel strength and foam formation ability, but its foam stability was the lowest. Nevertheless, spray-dried gelatin exhibited the best emulsion capacities.

FISH GELATIN

Fish gelatin from both cold- and warm-water fish has been extracted under different conditions (Table 21.2) (Montero and Gómez-Guillén 2000, Jamilah and Harvinder 2002, Cho et al. 2004, Muyonga et al. 2004, Zhou and Regenstein 2004, Cho et al. 2005, Jongjareonrak et al. 2006a, Arnesen and Gildberg 2007, Cheow et al. 2007, Yang et al. 2007, Nalinanon et al. 2008, Aewsiri et al. 2008, Giménez et al. 2009, Aewsiri et al. 2009a, Jongjareonrak et al. 2010, Kittiphattanabawon et al. 2010). However, gelatins from these sources have limited application as they have lower gel strength and their gels are less stable, compared with those from their mammalian counterparts. The differences between fish and mammalian gelatin mainly depend on their molecular weight distribution and amino acid content, especially the content of imino acid (proline and hydroxyproline) (Johnston-Banks 1990). However, gelatin from skin of brownbanded bamboo shark extracted under the appropriate conditions had properties similar to those of mammalian gelatin. The gel could be set at room temperature and had the bloom strength comparable to commercial bovine gelatin (Kittiphattanabawon

et al. 2010). This shark skin gelatin might contain similar amino acids, especially imino acids, as well as could form gel comparable to that from mammalian source.

FUNCTIONAL PROPERTIES OF GELATIN

Gelatin is a gelling protein, which has widely been applied in the food and pharmaceutical industries (Cho et al. 2005). Gelatin gel has "melt-in-the-mouth" characteristic and shows an excellent release of flavor (Choi and Regenstein 2000). Moreover, its functional properties, including gelation, emulsifying properties, foam-forming properties, and film formation, are important for the food industry as it enhances the elasticity, consistency, and stability of food products, and it is also used as an outer film to protect foods against light and oxygen (Montero and Gómez-Guillén 2000).

Gelation

An aqueous solution of gelatin becomes slightly viscous at temperature above its melting temperature. On cooling, the gelatin solution starts to form transparent elastic thermoreversible gels when the temperature is below the setting temperature (Normand et al. 2000, Babin and Dickinson 2001). The interaction initiates a disorder-to-order transition, as the random coil gelatin molecules seek to return to the ordered triple helix conformation. Gelatin gel is a reversibly cross-linked biopolymer network stabilized mainly by hydrogen-bonded junction zones (Fig. 21.2). Furthermore, hydrophobic and ionic interactions are also involved in the gelation of gelatin (Fig. 21.2). The gelation of gelatin is dependent on many factors such as source of raw material for gelatin extraction, presence of endogenous protease in raw material, and the conditions for gelatin extraction, particularly temperature, play a role in gelation of resulting gelatin. High temperature generally renders high yield, the gelatin so obtained has shorter chains (Kittiphattanabawon et al. 2010). These fragments cannot form the junction zone effectively. As a result, a poor gel is formed or gel of these fragments cannot set, especially at room temperature (25°C) (Fig. 21.2).

Source of Raw Material

The sources of raw materials influence the composition of gelatin, especially amino acid composition of gelatin, which affect gelling properties. Generally, the imino acid content of gelatin obtained from mammals is higher than that of gelatin from both warm-water and cold-water fish (Table 21.3). Imino acid content correlates with gel strength of gelatin. Imino acid, especially hydroxyproline, is involved in gel formation by acting as a H-donor, in which hydrogen bond can be formed with an adjacent chain possessing H-acceptor (Fig. 21.2). The hydroxyl group of the hydroxyproline plays a part in the stability of the helix by interchain hydrogen bonding via a bridging water molecule as well as direct hydrogen bonding to a carbonyl group (Wong 1989).

Fish gelatin has been recognized to exhibit poorer gelling properties than its mammalian counterpart. Gelatin from

brownbanded bamboo shark and blacktip shark extracted at 45°C for 6 hours exhibited higher bloom strength as compared to that of bovine gelatin. Additionally, gelatin from brownbanded bamboo shark can be set at room temperature within 3 hours (Kittiphattanabawon et al. 2010). This superior gelling ability is mainly attributed to the high imino acid content of gelatin from the skin of both sharks.

Presence of Endogenous Protease in Raw Material

Proteinases are enzymes inducing the cleavage of peptides. Collagenolytic enzyme is another proteinase, which catalyzes the hydrolysis of collagen and gelatin (Sikorski et al. 1990, Kristjánsson et al. 1995, Sovik and Rustad 2006). The major collagenolytic enzyme is collagenase, a group of matrix metalloproteinase in a family of zinc-dependent enzyme. Collagenase can cleave triple-helical collagen at a single site, resulting in the formation of fragments corresponding to one-fourth and three-fourth of its initial length (Sano et al. 2004). Metallocollagenase obtained from fibroblastic cells of rainbow trout was classified as MMP-13 (collagenase-3, EC 3.4.24) (Saito et al. 2000).

Recently, the presence of an endogenous protease—serine protease—in bigeye snapper skin has been reported (Jongjareonrak et al. 2006a, Intarasirisawat et al. 2007, Nalinanon et al. 2008). Intarasirisawat et al. (2007) reported that endogenous serine protease contributing to the autolysis of the skin of bigeye snapper had the maximal activity at 60°C, which is within the temperature range used for gelatin extraction. Nalinanon et al. (2008) reported that the gelatin extracted by the typical process in the absence of protease inhibitor—soybean trypsin inhibitor (SBTI)—showed lower gel strength as compared to that extracted in the presence of SBTI. When gelatin was extracted from the skin of bigeye snapper skin in the presence of SBTI, β- and α-chains along with the polymerized components were retained (Fig. 21.3). Gelatin molecules with the shorter chains generated by serine protease are not able to form the strong interjunction zone, especially via hydrogen bond or other weak bonds such as hydrophobic interaction or ionic interaction. As a consequence, a weaker network develops, in contrast to the gelatin molecules with longer chain length, which are capable of alignment or self-aggregation more effectively (Fig. 21.4).

Extraction Conditions

Most of the processes involved in gelatin extraction directly or partially affect the functional properties of gelatin. Pretreatment of fish skin has been reported to have an impact on gel-forming ability of gelatin. Gómez-Guillén and Montero (2001) extracted the gelatin from megrim skins pretreated with different organic acids including formic acid, acetic acid, propionic acid, lactic acid, malic acid, tartaric acid, and citric acid at a concentration of 0.05 M. Gelatin extracted from the skin pretreated with acetic acid and propionic acid exhibited the highest gel strength. Furthermore, the skin from dover sole swollen with 50-mM acetic acid produced gelatin with the highest gel strength as compared to that swollen in 25- and 50-mM lactic acid (Giménez et al. 2005). Ahmad and Benjakul (2011) reported that gelatin from
Figure 21.3. Protein patterns of gelatin extracted from bigeye snapper skin in the absence and the presence of soybean trypsin inhibitor (SBTI) at different concentrations. I and C denote calfskin collagen type I and gelatin extracted without protease inhibitor. (Adapted from Nalinanon et al. (2008).)

the skin of unicorn leatherjacket swollen with 0.2 M phosphoric acid (GPA) resulted in the decreasing major band intensity (α-, β-, and γ-chains) and the increasing low-molecular weight components occurred in comparison with that swollen with 0.2 M acetic acid (GAA). However, GPA exhibited higher bloom strength than GAA since some phosphate groups might attach with some amino acids during swelling process, leading to phosphorylation of GPA. Phosphorylation may introduce ionic interaction between phosphate groups and –NH$^+$ proton of amino acids, increasing the cross-links of proteins (Guo et al. 2005).

Extraction temperature and time are two other important factors affecting the gelation of gelatin. Generally, bloom strength of gelatin gel decreases as the extraction temperature and time increase. Normand et al. (2000) reported that higher extraction temperature caused protein degradation, producing protein fragments and lowering gelling ability. A weak gelatin gel was associated with the formation of small fragments (Gómez-Guillén et al. 2002). Degraded α-chains of gelatin are not able to anneal correctly during overnight stabilization by hindering the growth of the existing nucleation sites (Ledward 1986). Gómez-Guillén et al. (2002) found that squid gelatin extracted at 80°C showed very weak gel. For gelatin from Nile perch skin and bone, the gelatin extracted at 50°C exhibited higher gel strength than the corresponding bone gelatin. Gelatin extracted from skin of Nile perch at higher temperature exhibited lower gel strength, but temperature had no effect on gel strength of bone gelatin (Muyonga et al. 2004). Bloom strength of gelatin from brownbanded bamboo shark and blacktip shark decreased with increasing extraction temperature and time. The marked decrease in bloom
Figure 21.4. Impact of endogenous protease associated with fish skin on degradation of gelatin molecules.

strength was noticeable when extraction temperature of 75°C was used for extraction of gelatin from the skin of both sharks (Kittiphattanabawon et al. 2010).

EMULSIFYING AND FOAMING PROPERTIES

Emulsions and foams are heterogeneous systems consisting of one phase dispersed in another. An emulsion is a dispersion or suspension of two immiscible liquids, while a foam is a gas phase dispersed in liquid (Hill 1998). Proteins extracted from the different natural sources, for example, soy, milk, fish, meat, and plant, can be used as the emulsifier or foaming agents because of their ability to facilitate the formation and improve the stability of emulsion or foam (Surh et al. 2006). Gelatin is surface-active and is capable of acting as an emulsifier in oil-in-water emulsions and foaming agent (Lobo 2002, Cho et al. 2004, Surh et al. 2006, Aewsiri et al. 2008, Binsi et al. 2009, Kwak et al. 2009, Aewsiri et al. 2009a, Jongjareonrak et al. 2010). The hydrophobic areas on the peptide chain are responsible for giving gelatin its emulsifying and foaming properties (Galazka et al. 1999, Cole 2000). Gelatin concentration has an impact on interfacial properties, but these properties are also governed by the source of the raw material.

Aewsiri et al. (2008) reported that the higher emulsifying and foaming properties were observed in gelatin from precooked tuna fin when the concentration of gelatin was increased. In contrast, the emulsifying capacity of gelatin from bigeye snapper (*Priacanthus hamrur*) decreased with increasing gelatin concentration (Binsi et al. 2009). Additionally, Aewsiri et al. (2009a) studied the emulsifying properties, emulsion activity index (EAI) and emulsion stability index (ESI), and foaming properties, foam expansion (FE) and foam stability (FS) of gelatin from cuttlefish skin with and without bleaching using hydrogen peroxide (H_2O_2). Emulsions containing gelatin from bleached dorsal and ventral skin were more stable than those of gelatin without bleaching. A longer bleaching time and higher H_2O_2 concentration led to a lower ESI of gelatin for all samples, except for gelatin from dorsal skin in which the highest ESI was

obtained when the skin was bleached with 5% H_2O_2 for 48 hours ($p < 0.05$). Surh et al. (2006) found that the oil-in-water emulsion prepared with high-molecular weight fish gelatin ($\sim$120 kDa) was more stable than that prepared with low-molecular weight fish gelatin ($\sim$50 kDa). For foam-forming ability, gelatin from unbleached skin, both dorsal and ventral, had a slightly lower FE than gelatin extracted from bleached skin, while bleaching had no effect on the FS of gelatin from ventral skin, but gelatin from dorsal skin bleached with 5% H_2O_2 for 48 hours showed the highest FS (Aewsiri et al. 2009a). Jongjareonrak et al. (2010) reported that foam capacity and foam stability of gelatin from farmed giant catfish were higher than that from calfskin. Gelatin from shark cartilage and precooked tuna fin showed lower foam capacity and foam stability than gelatin from porcine skin (Cho et al. 2004, Aewsiri et al. 2008).

FILM FORMATION

Film and coating from biopolymers such as proteins and polysaccharides have been receiving increasing attention since synthetic packaging films have led to serious ecological problems because of their nonbiodegradability. Proteins are important biopolymers possessing good film-forming ability (Benjakul et al. 2008). Moreover, their mechanical and barrier properties are generally superior to polysaccharide-based films (Cuq et al. 1998). Among all proteins, gelatin has attracted the attention for the development of edible films due to its abundance, biodegradability, and excellent film-forming properties (Gennadios et al. 1994, Bigi et al. 2002). Thus, it is one of the first materials applied to edible coatings and films. The main parameters affecting film-forming properties of gelatin are the source of raw material, extraction method, molecular weight, film preparation method, and degree of hydration or type and level of plasticizer used (Jongjareonrak et al. 2006a, 2006b).

Giménez et al. (2009) suggested that giant squid gelatin obtained from pepsin aid process during the swelling step showed good film-forming properties. Its puncture force, puncture deformation, and water permeability were 4.94 N, 46%, and

1.89×10^{-8} g mm h^{-1} cm^{-2} Pa^{-1}, respectively. Zhang et al. (2007) characterized edible film from channel catfish gelatin extracted using different pretreatment methods. The pretreatment method with 0.25 M NaOH and 0.09 M acetic acid, followed by extraction at 50°C for 3 hours was selected as the optimum extraction method. The resultant film had tensile strength (TS), percentage elongation (%E), and water vapor permeability (WVP) comparable to the film obtained from commercial mammalian gelatin. Additionally, Nile perch skin gelatin films were also found to exhibit film strength (stress at break) and percentage of strain (elongation at break) similar to that of bovine bone gelatin (Muyonga et al. 2004).

TS and %E of catfish gelatin films significantly increased from 27.1 MPa to 61.7 MPa and from 105.1% to 115.1%, respectively, when the gelatin contents were increased from 0.5% to 1%. WVP also increased with the increase in gelatin contents from 0.5% to 2.5% (Zhang et al. 2007). TS and %E of skin-gelatin films of bigeye snapper increased with increasing protein concentration from 2% to 3%, but the increase in protein concentration did not affect WVP (Jongjareonrak et al. 2006a). Additionally, the decrease in TS and increase in %E and WVP were observed in the gelatin-based film from catfish, bigeye snapper, and brownstripe red snapper, when the concentration of glycerol was increased (Jongjareonrak et al. 2006a, Zhang et al. 2007). Generally, less stiff and rigid, more extensible films may be obtained by increasing the plasticizer concentration in the film, due to the reduction in interactions between the biopolymer chains (Arvanitoyannis 2002). Hoque et al. (2010) studied the effect of heat treatment, at different temperatures (40–90°C), of film-forming solution (FFS) containing 3% gelatin from cuttlefish ventral skin and 25% glycerol (based on protein) on film properties. The gelatin film prepared from FFS heated at 60°C and 70°C showed the highest TS ($p<0.05$), while that from FFS heated at 90°C had the highest elongation at break (EAB). Additionally, increasing heating temperatures resulted in the decrease in WVP of films, while L*-value and transparency value were not different. However, an increase in b*-value was observed with increasing heating temperature, mainly mediated by Maillard reaction at higher temperature (Manzoccu et al. 2000, Chinabhark et al. 2007).

IMPROVEMENT OF FUNCTIONAL PROPERTIES OF FISH GELATIN

Because of the inferior gel-forming ability of fish gelatin to its mammalian counterpart, fish gelatin can be subjected to modifications for gel improvement or be used for other functional properties. To increase or maximize its functional properties, the modification of gelatin by several methods or the addition of selected compounds has been implemented.

USE OF PROTEIN CROSS-LINKERS

Aldehydes

The reaction of glutaraldehyde with an amine group involves the formation of an imine followed (or preceded) by aldol

reactions (Monsan et al. 1975). Subsequent dehydration leads to stable unsaturated cross-links. The sugar-based counterpart of this process is known as the Maillard or browning reaction (Ellis 1959, Ledl and Schleicher 1990), the reaction between aldose sugars and amino groups. The first step in the Maillard reaction is the reversible formation of a glycosylamine that can undergo a so-called Amadori rearrangement (Hodge 1955) to 1-amino-1-deoxy-2-ketose, which will not hydrolyze under ambient conditions. A sugar aldehyde, therefore, can act as a protein cross-linker through glycation and Amadori rearrangement reactions (Schoevaart and Kieboom 2002). The aldehydes commonly used include glutaraldehyde, formaldehyde, and glyoxal (Marquie et al. 1995). However, there are indications of possible toxicity, which make it questionable to use as the modifying agents in foods (Lam et al. 1986, Galietta et al. 1998).

Phenolic Compounds

Phenolic compounds as food components represent more than 6000 identified substances and have been known as the largest group of secondary metabolites in plant foods (Rawel et al. 2007). They generally possess an aromatic ring bearing one or more hydroxy substituents (Robards et al. 1999). They are usually found in plants and are bound to sugars as glycosides (Hollman and Arts 2000). Phenolic compounds can interact with proteins in two different ways: via noncovalent (reversible) interactions and via covalent interactions, which in most cases are irreversible (Prigent 2005). Hydrogen bonds may involve the interactions between hydroxyl groups of phenolic compounds and the nitrogen or oxygen of lysine, arginine, histidine, asparagine, glutamine, serine, threonine, aspartic acid, glutamic acid, tyrosine, cysteine, and tryptophan. Hydrophobic interactions may occur between phenolic compounds and amino acids such as alanine, valine, isoleucine, leucine, methionine, phenylalanine, tyrosine, tryptophan, cysteine, and glycine residues (Prigent 2005).

Covalent interactions between phenolic compounds and proteins can occur via oxidation of phenolic compounds to radicals or quinones (Balange and Benjakul 2009). Monophenol and polyphenol are readily oxidized to *ortho*-quinone, either enzymatically as in plant tissues, or by molecular oxygen. The quinone forms a dimer through a secondary reaction, or reacts with amino or sulfhydryl side chains of polypeptides to form covalent C–N or C–S bonds with the phenolic ring (Fig. 21.5) (Strauss and Gibson 2004). However, gelatin contains a negligible content of cysteine. Thus, the cross-links formed are mainly via amino groups, in which covalent bonds can be formed. Lysine in gelatin molecule could provide ε-NH$_3$ as the binding site in this reaction. Fish gelatin had lysine ranging from 12 to 32 residues/1000 residues (Table 21.3). Polyphenols can be reoxidized and bind a second polypeptide. As a consequence, protein cross-links can be formed (Fig. 21.5).

Strauss and Gibson (2004) prepared oxidized phenolic compounds–gelatin mixtures by adjusting pH to 8 followed by mixing with gelatin in the presence of oxygen at 40°C. Gels so obtained had greater mechanical strength, reduced swelling,
Figure 21.5. Reaction between phenolic compounds and side chain of gelatin.

and fewer free amino groups. Dynamic light scattering analyses showed that such cross-linking results in denser polymeric networks. Aewsiri et al. (2009b) reported that cuttlefish skin gelatin modified with oxidized phenolic compounds, including ferulic acid and tannic acid, at the level above 5% (w/w of protein) exhibited a decrease in the emulsion activity index (EAI). This was possibly associated with the decrease in surface hydrophobicity of the modified gelatin.

Genipin

Genipin is a hydrolytic product of geniposide and its related iridoid glucosides, which are extracted from the fruits of *Gardenia jasminoides Ellis* (Yao et al. 2004) via enzymatic hydrolysis with β-glucosidase (Butler et al. 2003). Genipin has been known as a naturally occurring cross-linking agent (Nickerson et al. 2006b).

Genipin participates in both short- and long-range covalent cross-linking of ε-amino groups in amine-containing polymers (Nickerson et al. 2006a). It can react with amino acid or proteins in the presence of oxygen to form dark blue pigments used in the fabrication of food dyes (Touyama et al. 1994). Additionally, it can form stable cross-linked products with resistance against

enzymatic degradation, comparable to that of glutaraldehyde-fixed tissue (Huang et al. 1998, Sung et al. 1998). Furthermore, gelatin-derived bioadhesives display higher biocompatibility and less cytotoxicity when cross-linked with genipin than with other agents, such as formaldehyde, glutaraldehyde, and epoxy compounds (Sung et al. 1999). The mechanism of the reaction of amino acids or proteins with genipin is proposed by Touyama's group (Touyama et al. 1994a, 1994b). The formation of the genipin–methylamine monomer is through a nucleophilic attack by methylamine on the olefinic carbon at C-3 in genipin, followed by the opening of the dihydropyran ring and an attack by the secondary amino group on the resulting aldehyde group. The blue-pigment polymers are presumably formed through the oxygen radical-induced polymerization and dehydrogenation of several intermediary pigments.

Yao et al. (2004) reported that genipin is a good cross-linker for the gelatin. The rate of degradation and the degree of cross-linking of the genipin-fixed gelatin depend upon genipin concentration. Moreover, increasing genipin concentration makes the gelatin network gradually shift from being dominated by hydrogen bonds to covalent cross-linking (Nickerson et al. 2006b). However, the concentration of genipin should exceed 0.5% (w/v) of the overall weight of the gelatin-based material (25% (w/v))

if a complete cross-linking reaction between gelatin and genipin molecules is required (Yao et al. 2004).

Transglutaminase

Transglutaminase (TGase; protein-glutamine-glutamyltransferase, EC 2.3.2.13) catalyzes an acyl-transfer reaction between the γ-carboxamide group of peptide-bound glutamine residues (acyl donors) and a variety of primary amines (acyl acceptors), including the ε-amino group of lysine residues in certain proteins (Fig. 21.6). It results in polymerization and inter- or intramolecular cross-linking of protein via formation of ε-(γ-glutamyl)lysine linkages (Motoki and Seguro 1998, Ashie and Lanier 2000). In the absence of amine substrates, water may act as the acyl acceptor, resulting in deamidation of γ-carboxamide group of glutamine to form glutamic acid. Formation of covalent cross-links between proteins is the basis of the ability of TGase to modify the physical properties of food protein (Ashie and Lanier 2000). TGases are widely distributed in most animal tissues and body fluids, and are involved in several biological phenomena, such as blood clotting, wound healing, epidermal keratinization, and stiffening of the erythrocyte membrane (Aeschlimann and Paulsson 1994). They are responsible for the regulation of cellular growth, differentiation, and proliferation. TGases have also been discovered in plants (Icekson and Apelbaum 1987), fish (Araki and Seki 1993), and microorganisms (Ando et al. 1989, Klein et al. 1992).

Microbial transglutaminase (MTGase) are mass-produced at low cost by fermentation. MTGase catalyzes the cross-linking of most food proteins through the formation of an ε-(γ-glutamyl)lysine bond, in the same way as well-known mammalian enzymes. MTGase is calcium independent and its molecular weight is smaller than that of other known enzymes (Motoki and Seguro 1998). The results of many studies suggest that MTGase, as well as other transglutaminases, has many potential applications in food processing and other areas.

Babin and Dickinson (2001) studied the influence of transglutaminase cross-linking on the rheology of gelatin gels. The gel strength might be either reduced or enhanced depending on whether covalent cross-linking occurred predominantly before or after the development of triple helix junction zones. The extensive covalent cross-linking occurred during cold-set process, and afterward in the molten state, thermoreversible character of gelatin gel was almost completely lost.

Jongjareonrak et al. (2006c) studied the effect of microbial transglutaminase (MTGase) on the gel properties of gelatin from bigeye snapper skin and brownstrip red snapper skin. The addition of MTGase at concentrations up to 0.005% and 0.01% (w/v) increased the bloom strength of gelatin gel from bigeye snapper and brownstripe red snapper, respectively. However, the bloom strength of gelatin gel from both fish species decreased with further increase in MTGase concentration. Gómez-Guillén et al. (2001) reported that the addition of microbial transglutaminase to a fish skin gelatin can considerably raise melting point, gel strength, and viscosity at 60°C, depending on the concentration of the enzyme and the incubation time. Increasing concentrations of TGase increase the elasticity and cohesiveness of the gels, but result in lower gel strength and hardness because they produce excessively rapid gel network formation (Gómez-Guillén et al. 2001). Recently, Norziah et al. (2009) reported that the addition of MTGase with the concentration of 0.5 and 1.0 mg/g gelatin into fish gelatin extracted from the wastes of fish herring species (*Tenualosa ilisha*) had higher gel strength than that without the addition of enzyme, while enzyme concentration above 1.0 mg/g gelatin resulted in a decreasing gel strength. Adding a high concentration of TGase or cross-linking before gelation would be detrimental to gel strength (Babin and Dickinson 2001). Regenstein and Zhou (2007a) also suggested that TGase should not be added over an appropriate enzyme concentration. The reaction should occur during or after gel development to obtain the desired cross-linking. Additionally, Fernandez-Diaz et al. (2001) reported that the gelatin from hake skin had the highest bloom strength with the addition of 10 mg transglutaminase/g.
Figure 21.6. Cross-linking reaction between glutamine and lysine residues induced by transglutaminase.

USE OF HYDROCOLLOIDS

Food products are composed of a wide range of ingredients such as proteins and carbohydrate-based polysaccharides (Ye 2008).

Complex formation between proteins and polysaccharides occurs at pH values below the isoelectric point (IEP) of the proteins and at low ionic strength, usually <0.3 (Ye 2008). Protein molecules have a net positive charge and behave as polycations at pH values below the IEP (De Kruif et al. 2004). At mildly acidic and neutral pH values, which are typical of most foods, carboxyl-containing polysaccharides behave as polyanions (Ye 2008). Electrostatic complex formation between proteins and anionic polysaccharides generally occurs in the pH range between the pK_a value of the anionic groups (carboxyl groups) on the polysaccharide and the IEP of the protein (Tolstoguzov 1997).

The mixtures of fish gelatin and κ-carrageenan had the gels with varying degree of turbidity, depending on the concentration of polymers, pH, ionic strength, and the nature of the added salt (Haug et al. 2004). The highest gel strength was found when 20 mM KCl and 20 mM NaCl were added into the mixtures of 1% (w/v) κ-carrageenan with 2% and 5% (w/v) fish gelatin, respectively. However, these mixtures exhibited more turbid gel than κ-carrageenan or fish gelatin alone since the system undergoes associative phase separation promoted by the release of counterions (Piculell et al. 1995). Complexes of fish gelatin and κ-carrageenan at 60°C were probably stabilized by electrostatic interactions and the solutions were highly turbid, and at 4°C the strongest gel was obtained (Haug et al. 2004).

Liu et al. (2007a) determined the hardness of gelatin/pectin mixed gels with different ratios. The addition of pectin resulted in the increased gel hardness. The strong interactions between two polymers in the mixed solution resulted in a synergistic effect. At the same gelatin content, the lower pectin content added to the system resulted in a harder gel. The excess pectin content formed the repulsive forces in the junction zones, which might reduce the formation of linkages between the aggregated helices, leading to weakened gel structures (Liu et al. 2007a).

OXIDATION PROCESS

Free radical-mediated protein modification affects protein functionalities. Protein oxidation can lead to the formation of several different kinds of protein cross-links (Stadtman 1998). For example, abstraction of H atoms from protein by radical could result in the reaction with one another to form –C–C– protein cross-linked products. The oxidation of protein sulfhydryl groups can lead to disulfide –S–S– cross-linked proteins. Additionally, the carbonyl groups obtained by the direct oxidation of amino acid side chains of one protein may react with the lysine amino groups of another protein to form Schiff-based cross-linked products.

Fenton reaction, involving a mixture of ferrous ion (Fe^{2+}) and H_2O_2, generates hydroxyl radicals ($HO^\bullet$) at room temperature (Walling 1975, Fenton 1984) as shown in equation below:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^\bullet + OH^-$$

H_2O_2 is largely used in oxidation process. Its oxidizing properties are not only due to the presence of an active oxygen atom in the molecule, but also to its ability to participate in radical reactions, with the homolysis of the O–O bond, leading to the formation of the $HO^\bullet$ radical (Chedeville et al. 2005). $HO^\bullet$ radical can oxidize organic compounds in solution (Namkung et al. 2008).

Aewsiri et al. (2009a) reported that uses of H_2O_2 for bleaching of cuttlefish skin prior to gelatin extraction could improve the bloom strength of gelatin gel. H_2O_2 might induce the oxidation of protein with the concomitant formation of carbonyl groups. Those carbonyl groups might undergo Schiff base formation with the amino groups, in which the protein cross-links were most likely formed (Stadtman 1997). Moreover, $OH^\bullet$ can abstract H atoms from amino acid residues to form carbon-centered radical derivatives, which can react with one another

to form C–C protein cross-linked products (Stadtman 1997). The larger protein aggregates were mostly associated with the improved bloom strength.

Additionally, free radical in protein could be generated by irradiation, such as UV-irradiation and gamma-irradiation. Irradiation makes protein oxidized, followed by the generation of free radical, resulting in either cross-linking (protein aggregation) or degradation of protein. Bhat and Karim (2009) reported that gelatin treated with UV-irradiation for 60 minutes prior to preparing the gel showed higher gel strength than the gelatin treated with UV-irradiation for 30 minutes as well as that without any UV-irradiation, respectively. Bessho et al. (2007) reported that insolubility due to cross-linking of the gelatin hydrogels was induced at doses above 8 kGy gamma-irradiation. Hydrocarbon groups (alkyl or a phenyl group of the side chains) are the cross-linking sites of gelatin hydrogels.

APPLICATIONS OF GELATIN

Gelatin has been used widely in many sections of the food industry. The major uses cover jellies, confectionery, meat products, and chilled dairy products. It can be used in the pharmaceutical industry, especially for hard and soft capsule manufacture and in the photographic industry, which uses the unique combination of gelling agent and surface activity to suspend particles of silver chloride or light-sensitive dyes (Kragh 1977, Fiszman et al. 1999, Soper 1999, Choi and Regenstein 2000, Park et al. 2007, Zhou and Regenstein 2007, Cheng et al. 2008, Binsi et al. 2009).

Due to the drawbacks of fish gelatin—that it does not gel at room temperature and requires temperature below 8–10°C for setting, it can also be used in other applications that do not require a high bloom value such as for prevention of syneresis and modification of food texture. Fiszman et al. (1999) studied the effect of the addition of gelatin on the microstructure of acid milk gels and yogurt and on their rheological properties. The addition of 1.5% gelatin developed fairly firm and deformable gels with almost total absence of syneresis. Dynamic rheology showed that the yogurts with added gelatin exhibited more solid-like behavior than the ones prepared without it.

Gelatins from tuna or tilapia skin (warm-water fish) have a melting point of 25–27°C (Choi and Regenstein 2000) and have a bloom value of 200–250 g. These gelatins more closely resemble bovine or pig gelatin, which melts at 32–35°C. Fish gelatin with lower gel melting temperatures had a better release of aroma and offered a stronger flavor (Choi and Regenstein 2000). By increasing the concentration of gelatin or by using gelatin mixtures, desserts made from fish gelatins would be more similar to desserts made from high bloom pork skin gelatin (Zhou and Regenstein 2007).

Cheng et al. (2008) observed that combinations of fish gelatin with pectin have been used to make a low-fat spread. A decrease in the fish gelatin to pectin ratio (3:0, 2:1, 1:1, and 1:2) resulted in an increase in bulk density, firmness, compressibility, adhesiveness, elasticity, and meltability. On the other hand, use of gelatin/sodium alginate blends to form casings could lower water losses and lipid oxidation during chilled storage as compared to pectin casing (Liu et al. 2007b). Recently, Binsi et al.

(2009) used gelatin from the skin of bigeye snapper (*Priacanthus hamrur*) to modify the texture of threadfin bream mince gel. The addition of fish gelatin (0.1–1%) to fish mince resulted in higher storage modulus (G′) values from the beginning of heating regime. A maximum G′ value of 443.7 kPa at 68.3°C was obtained in the presence of 0.5% gelatin, which was 42% higher than that of fish mince without the added gelatin.

Fish gelatins with low melting points could also be used in dry products. One of the major applications of fish gelatin is in the microencapsulation of vitamins and other pharmaceutical additives. Soper (1999) described a method for microencapsulation of food flavors such as vegetable oil, lemon oil, garlic flavor, apple flavor, or black pepper with warm-water fish gelatin (150–300 bloom). Park et al. (2007) patented a process describing the preparation of a film-forming composition for hard capsules composed of fish gelatin. Using transglutaminase for cross-linking circumvented the problems caused by the low gelling temperature property of fish gelatin.

Application of Proteomics to Fish Processing and Quality

Hólmfríður Sveinsdóttir, Samuel A. M. Martin, and Oddur T. Vilhelmsson

Abstract: Proteomics involves the study of proteins, with regards to proteins, their expression by genomes, their structures and functions. The entire set of proteins or proteome expressed by a genome display variations in tissues and organisms, and can be used as the basis for evaluating the status and changes in the proteins in living organisms including fish and shellfish. This feature can be useful for developing standards for fish and other food materials and assessing their quality and/or safety. This chapter discusses current uses of proteomics for establishing the attributes of fish and fish products.

Proteomics is most succinctly defined as "the study of the entire proteome or a subset thereof," the proteome being the expressed protein complement of the genome. Unlike the genome, the proteome varies among tissues, as well as with time in reflection of the organism's environment and its adaptation thereto. Proteomics can, therefore, give a snapshot of the organism's state of being and, in principle at least, map the entirety of its adaptive potential and mechanisms. As with all living matter, foodstuffs are in large part made up of proteins. This is especially true of fish and meat, where the bulk of the food matrix is constructed from proteins. Furthermore, the construction of the food matrix, both on the cellular and tissue-wide levels, is regulated and brought about by proteins. It stands to reason, then, that proteomics is a tool that can be of great value to the food scientist, giving valuable insight into the composition of the raw materials, quality involution within the product before, during, and after processing or storage, the interactions of proteins with one another or with other food components, or with the human immune system after consumption. In this chapter, a brief overview of "classical" proteomics methodology is presented, and their present and future application in relation to fish and seafood processing and quality is discussed.

PROTEOMICS METHODOLOGY

Unlike nucleic acids, proteins are an extremely variegated group of compounds in terms of their chemical and physical properties. It is not surprising, then, that a field that concerns itself with "the systematic identification and characterization of proteins for their structure, function, activity and molecular interactions" (Peng et al. 2003) should possess a toolkit containing a wide spectrum of methods that continue to be developed at a brisk pace. While high-throughput, gel-free methods, for example, based on liquid chromatography tandem mass spectrometry (LC-MS/MS) (Peng et al. 2003), surface-enhanced laser desorption/ionization (Hogstrand et al. 2002), or protein arrays (Lee and Nagamune 2004), hold great promise and are deserving of discussion in their own right, the "classic" process of
Figure 22.1. An overview over the "classic approach" in proteomics. First, a protein extract (crude or fractionated) from the tissue of choice is subjected to two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). Once a protein of interest has been identified, it is excised from the gel, subjected to degradation by trypsin (or other suitable protease) and the resulting peptides analyzed by mass spectrometry (MS), yielding a peptide mass fingerprint. In many cases, this is sufficient for identification purposes, but if needed, peptides can be dissociated into smaller fragments and small partial sequences obtained by tandem mass spectrometry (MS/MS). See text for further details.

two-dimensional electrophoresis (2DE) followed by protein identification via peptide mass fingerprinting of trypsin digests (Fig. 22.1) remains the workhorse of most proteomics work, largely because of its high resolution, simplicity, and mass accuracy. This "classic approach" will, therefore, be the main focus of this chapter. A number of reviews on the advances and prospects of proteomics within various fields of study are available. Some recent ones include: Andersen and Mann (2006), Balestrieri et al. (2008), Beretta (2009), Bogyo and Cravatt (2007), Drabik et al. (2007), Ikonomou et al. (2009), Issaq and Veenstra (2008), Jorrin-Novo et al. (2009), Latterich et al. (2008), López (2007), Mamone et al. (2009), Malmstrom et al. (2007), Premsler et al. (2009), Smith et al. (2009), Wang et al. (2006), Wilm (2009), Yates et al. (2009).

Two-Dimensional Electrophoresis

2DE, the cornerstone of most proteomics research, is the simultaneous separation of hundreds, or even thousands, of proteins on a two-dimensional polyacrylamide slab gel. The potential of a two-dimensional protein separation technique was realized early on, with considerable development efforts taking place in the 1960s (Margolis and Kenrick 1969, Kaltschmidt and Wittmann 1970). The method most commonly used today was developed by Patrick O'Farrell. It is described in his seminal and thorough 1975 paper (O'Farrell 1975) and is outlined briefly later. It is worth emphasizing that great care must be taken that the proteome under investigation is reproducibly represented on the 2DE gels, and that individual variation in specific protein
Figure 22.2. A two-dimensional electrophoresis protein map of rainbow trout (*Oncorhynchus mykiss*) liver proteins with pI between 4 and 7 and molecular mass about 10–100 (S. Martin, unpublished). The proteins are separated according to their pI in the horizontal dimension and according to their mass in the vertical dimension. Isoelectro focussing was by pH 4–7 immobilized pH gradient (IPG) strip and the second dimension was in a 10–15% gradient polyacrylamide slab gel.

abundance is taken into consideration by running gels from a sufficient number of samples and performing the appropriate statistics. Pooling samples may also be an option, depending on the type of experiment.

Basic 2DE Methods Overview

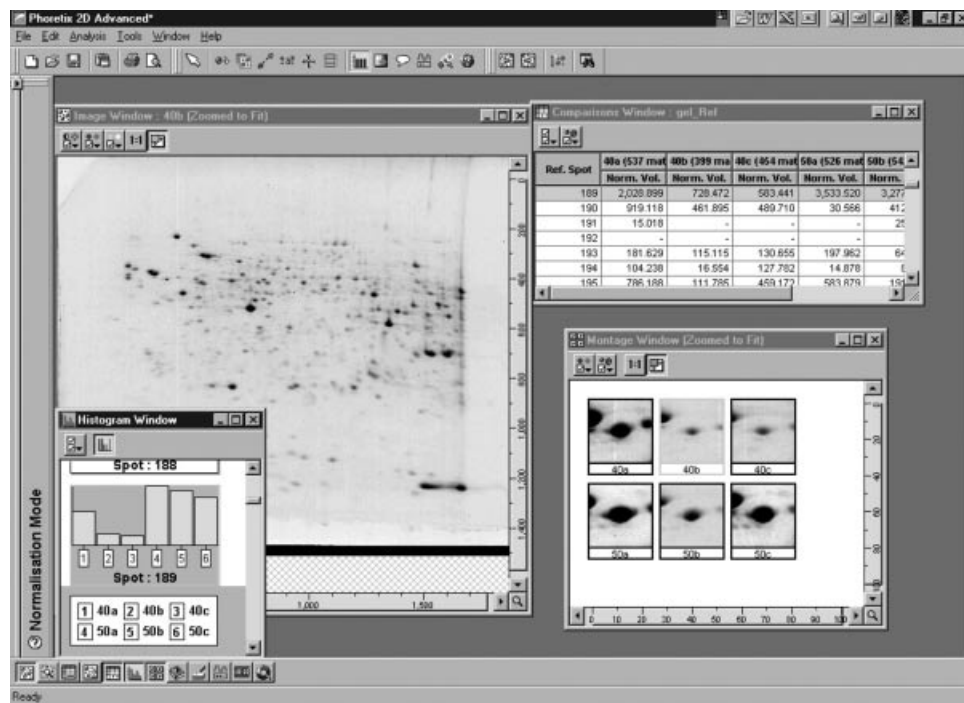
O'Farrell's original 2DE method first applies a process called isoelectric focusing (IEF), where an electric field is applied to a tube gel on which the protein sample and carrier ampholytes have been deposited. This separates the proteins according to their molecular charge. The tube gel is then transferred onto a polyacrylamide slab gel and the isoelectrically focused proteins are further separated according to their molecular mass by conventional sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), yielding a two-dimensional map (Fig. 22.2) rather than the familiar banding pattern observed in one-dimensional SDS-PAGE. The map can be visualized and individual proteins quantified by radiolabeling or by using any of a host of protein dyes and stains, such as Coomassie blue, silver stains, or fluorescent dyes. By comparing the abundance of individual proteins on a number of gels (Fig. 22.3), upregulation or downregulation of these proteins can be inferred. Although a number of refinements have been made to 2DE since O'Farrell's paper, most notably, the introduction of immobilized pH gradients (IPGs) for IEF (Görg et al. 1988), the procedure


Figure 22.3. A screenshot from the two-dimensional electrophoresis analysis program Phoretix 2-D (NonLinear Dynamics, Gateshead, Tyne & Wear, UK) showing some steps in the analysis of a two-dimensional protein map. Variations in abundance of individual proteins, as compared with a reference gel, can be observed and quantified.

remains essentially as outlined earlier. In the following sections, a general protocol is outlined briefly with some notes of special relevance to the seafood scientist. For more detailed, up-to-date protocols, the reader is referred to any of a number of excellent reviews and laboratory manuals such as Berkelman and Stenstedt (1998), Görg et al. (2000, 2004), Kraj and Silberring (2008), Link (1999), Simpson (2003), Walker (2005) and Westermeier and Naven (2002).

Sample Extraction and Cleanup

For most applications, sample treatment prior to electrophoresis should be minimal in order to minimize in-sample proteolysis and other sources of experimental artifacts. We have found direct extraction into the gel reswelling buffer (7-M urea, 2-M thiourea, 4% (w/v) CHAPS [3-(3-chloramidopropyl)dimethylamino-1-propanesulfonate], 0.3% (w/v) DTT [dithiothreitol], 0,5% Pharmalyte ampholytes for the appropriate pH range), supplemented with a protease inhibitor cocktail, to give good results for proteome extraction from whole Atlantic cod larvae (Guðmundsdóttir and Sveinsdóttir 2006, Sveinsdóttir et al. 2008) and Arctic charr (*Salvelinus alpinus*) liver (Coe and Vilhelmsson 2008). Thorough homogenization is essential to ensure complete and reproducible extraction of the proteome. Cleanup of samples using commercial two-dimensional sample cleanup kits may be beneficial for some sample types.

First-Dimension Electrophoresis

The extracted proteins are first separated by IEF, which is most conveniently performed using commercial dry IPG gel strips. These strips consist of a dried IPG-containing polyacrylamide gel on a plastic backing. Ready-made IPG strips are currently available in a variety of linear and sigmoidal pH ranges. This method is thus suitable for most 2DE applications and has all but completely replaced the older and less reproducible method of IEF by carrier ampholytes in tube gels. Broad-range linear strips (e.g., pH 3–10) are commonly used for whole-proteome analysis of tissue samples, but for many applications narrow-range and/or sigmoidal IPG strips may be more appropriate as these will give better resolution of proteins in the fairly crowded pI 4–7 range. Narrow-range strips also allow for higher sample loads (since part of the sample will run off the gel) and thus may yield improved detection of low-abundance proteins.

Before electrophoresis, the dried gel needs to be reswelled to its original volume. A recipe for a typical reswelling buffer is presented earlier. Reswelling is normally performed overnight at 4°C. Application of a low-voltage current may speed up the reswelling process. Optimal conditions for reswelling are normally provided by the IPG strip manufacturer. If the protein sample is to be applied during the reswelling process, extraction directly into the reswelling buffer is recommended.

IEF is normally performed for several hours at high voltage and low current. Typically, the starting voltage is about 150 V, which is then increased step-wise to about 3500 V, usually totaling about 10,000 to 30,000 Vh, although this will depend on the IPG gradient and the length of the strip. The appropriate IEF protocol will depend not only on the sample and IPG strip, but also on the equipment used. The manufacturer's instructions should be followed. Görg et al. (2000) reviewed IEF for 2DE applications.

Equilibration

Before the isoelectrofocused gel strip can be applied to the second-dimension slab gel, it needs to be equilibrated for 30–45 minutes in a buffer containing SDS and a reducing agent such as DTT. During the equilibration step, the SDS–polypeptide complex that affords protein-size-based separation will form and the reducing agent will preserve the reduced state of the proteins. A tracking dye for the second electrophoresis step is also normally added at this point. A typical equilibration-buffer recipe is as follows: 50 mM Tris-HCl at pH 8.8, 6-M urea, 30% glycerol, 2% SDS, 1% DTT, and trace amount of bromophenol blue. A second equilibration step in the presence of 2.5% iodoacetamide and without DTT (otherwise identical buffer) may be required for some applications. This will alkylate thiol groups and prevent their reoxidation during electrophoresis, thus reducing vertical streaking (Görg et al. 1987).

Second-Dimension Electrophoresis

Once the gel strip has been equilibrated, it is applied to the top edge of an SDS-PAGE slab gel and cemented in place using a molten agarose solution. Optimal pore size depends on the size of the target proteins, but for most applications gradient gels or gels of about 10% or 12% polyacrylamide are appropriate. Ready-made gels suitable for analytical 2DE are available commercially. While some reviewers recommend alternative buffer systems (Walsh and Herbert 1999), the Laemmli method (Laemmli 1970), using glycine as the trailing ion and the same buffer (25-mM Tris, 192-mM glycine, 0.1% SDS) at both electrodes, remains the most popular one. The gel is run at a constant current of 25 mA until the bromophenol blue dye front has reached the bottom of the gel.

Staining

Visualization of proteins spots is commonly achieved through staining with colloidal Coomassie Blue G-250 due to its low cost and ease of use. A typical staining procedure includes fixing the gel for several hours in 50% ethanol/2% *ortho*-phosphoric acid, followed by several 30-minute washing steps in water, followed by incubation for 1 hour in 17% ammonium sulfate/34% methanol/2% *ortho*-phosphoric acid, followed by staining for several days in 0.1% Coomassie Blue G-250/17% ammonium sulfate/34% methanol/2% *ortho*-phosphoric acid, followed by destaining for several hours in water. There are, however, commercially available colloidal Coomassie staining kits that do not require fixation or destaining.

A great many alternative visualization methods are available, many of which are more sensitive than colloidal Coomassie and thus may be more suitable for applications where visualization of low-abundance proteins is important. These include

radiolabeling, such as with [^{35}S]methionine, and staining with fluorescent dyes such as the SYPRO or Cy series of dyes. Multiple staining with dyes fluorescing at different wavelengths offers the possibility of differential display, allowing more than one proteome to be compared on the same gel, such as in difference gel electrophoresis (DIGE). Patton published a detailed review of visualization techniques for proteomics (Patton 2002).

Analysis

Although commercial 2DE image analysis software, such as ImageMaster (Amersham), PDQuest (BioRad), or Progenesis (Nonlinear Dynamics), has improved by leaps and bounds in recent years, analysis of the 2DE gel image, including protein spot definition, matching, and individual protein quantification, remains the bottleneck of 2DE-based proteome analysis and still requires a substantial amount of subjective input by the investigator (Barrett et al. 2005). In particular, spot matching between gels tends to be time consuming and has proved difficult to automate (Wheelock and Goto 2006). These difficulties arise from several sources of variation among individual gels, such as protein load variability due to varying IPG strip reswelling or protein transfer from strip to slab gel. Also, gene expression in several tissues varies considerably among individuals of the same species, and therefore individual variation is a major concern and needs to be accounted for in any statistical treatment of the data. Pooling samples may also be an option, depending on the type of experiment. These multiple sources of variation has led some investigators (Barrett et al. 2005, Karp et al. 2005, Wheelock and Goto 2006) to cast doubt on the suitability of univariate tests such as the Student's t-test, commonly used to assess the significance of observed protein expression differences. Multivariate analysis has been successfully used by several investigators in recent years (Gustafson et al. 2004, Karp et al. 2005, Kjaersgard et al. 2006b).

Some Problems and Their Solutions

The high resolution and good sensitivity of 2DE are what make it the method of choice for most proteomics work, but the method nevertheless has several drawbacks. The most significant of these have to do with the diversity of proteins and their expression levels. For example, hydrophobic proteins do not readily dissolve in the buffers used for isoelectrofocussing. This problem can be overcome, though, using nonionic or zwitterionic detergents, allowing for 2DE of membrane- and membrane-associated proteins (Chevallet et al. 1998, Herbert 1999, Henningsen et al. 2002, Babu et al. 2004). Vilhelmsson and Miller (2002), for example, were able to use "membrane protein proteomics" to demonstrate the involvement of membrane-associated metabolic enzymes in the osmoadaptive response of the foodborne pathogen *Staphylococcus aureus*. A 2DE gel image of *S. aureus* membrane-associated gels is shown in Figure 22.4.

Similarly, resolving alkaline proteins, particularly those with pI above 10, on two-dimensional gels has been problematic in the
Figure 22.4. A two-dimensional electrophoresis membrane proteome map from *Staphylococcus aureus,* showing proteins with pI between 3 and 10 and molecular mass about 15–100 (O. Vilhelmsson and K. Miller, unpublished). Isoelectrofocussing was in the presence of a mixture of pH 5–7 and pH 3–10 carrier ampholytes and the second dimension was in a 10% polyacrylamide slab gel with a 4% polyacrylamide stacker.

past. Although the development of highly alkaline, narrow-range IPGs (Bossi et al. 1994) allowed reproducible two-dimensional resolution of alkaline proteins (Görg et al. 1997), their representation on wide-range 2DE of complex mixtures such as cell extracts remained poor. Improvements in resolution and representation of alkaline proteins on wide-range gels have been made (Görg et al. 1999), but nevertheless an approach that involves several gels, each of a different pH range, from the same sample is advocated for representative inclusion of alkaline proteins when studying entire proteomes (Cordwell et al. 2000). Indeed, Cordwell and coworkers were able to significantly improve the representation of alkaline proteins in their study on the relatively highly alkaline *Helicobacter pylori* proteome using both pH 6–11 and pH 9–12 IPGs (Bae et al. 2003).

A second drawback of 2DE has to do with the extreme difference in expression levels of the cell's various proteins, which can be as much as 10,000-fold. This leads to swamping of low-abundance proteins by high-abundance ones on the two-dimensional map, rendering analysis of low-abundance proteins difficult or impossible. For applications such as species identification or study of the major biochemical pathways, where the proteins of interest are present in relatively high abundance,

this does not present a problem. However, when investigating, for example, regulatory cascades, the proteins of interest are likely to be present in very low abundance and may at times be undetectable because of the dominance of high-abundance ones. Simply increasing the amount of sample is usually not an option, as it will give rise to overloading artifacts in the gels (O'Farrell 1975). In transcriptomic studies, where a similar disparity can be seen in the abundance of RNA transcripts present, this problem can be overcome by amplifying the low-abundance transcripts using the polymerase chain-reaction, but no such technique is available for proteins. The remaining option, then, is fractionation of the protein sample in order to weed out the high-abundance proteins, allowing a larger sample of the remaining proteins to be analyzed. A large number of fractionation protocols, both specific and general, are available. Thus, Østergaard and coworkers used acetone precipitation to reduce the abundance of hordeins present in barley (*Hordeum vulgare*) extracts (Østergaard et al. 2002) whereas Locke and coworkers used preparative isoelectrofocussing to fractionate Chinese snow pea (*Pisum sativum macrocarpon*) lysates into fractions covering three pH regions (Locke et al. 2002). The fractionation method of choice will depend on the specific requirements of the study and on the tissue being studied. Discussion of some fractionation methods can be found in Ahmed (2009), Bodzon-Kulakowska et al. (2007), Butt et al. (2001), Canas et al. (2007), Corthals et al. (1997), Dreger (2003), Fortis et al. (2008), Issaq

et al. (2002), Lee and Pi (2009), Lopez et al. (2000), Millea and Krull (2003), Pieper et al. (2003), Righetti et al. (2005a, b) Rothemund et al. (2003), von Horsten (2006).

IDENTIFICATION BY PEPTIDE MASS FINGERPRINTING

Identification of proteins on 2DE gels is most commonly achieved via mass spectrometry (MS) of trypsin digests. Briefly, the spot of interest is excised from the gel, digested with trypsin (or another protease), and the resulting peptide mixture is analyzed by MS. The most popular MS method is matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) MS (Courchesne and Patterson 1999), where peptides are suspended in a matrix of small, organic, ultraviolet-absorbing molecules (such as 2,5-dihydroxybenzoic acid) followed by ionization by a laser at the excitation wavelength of the matrix molecules and acceleration of the ionized peptides in an electrostatic field into a flight tube where the time of flight of each peptide is measured, giving its expected mass.

The resulting spectrum of peptide masses (Fig. 22.5) is then used for protein identification by searching against expected peptide masses calculated from data in protein sequence databases, such as SwissProt or the National Centre for Biotechnology Information (NCBI) nonredundant protein sequences data base, using the appropriate software. Several programs are available, many with a web-based open-access interface. The ExPASy
Figure 22.5. A trypsin digest mass spectrometry fingerprint of a rainbow trout liver protein spot, identified as apolipoprotein A I-1 (S. Martin, unpublished). The open arrows indicate mass peaks corresponding to trypsin self-digestion products and were, therefore, excluded from the analysis. The solid arrows indicate the peaks that were found to correspond to expected apolipoprotein A I-1 peptides.

Tools website (http://www.expasy.org/tools) contains links to most of the available software for protein identification and several other tools. Attaining a high identification rate is problematic in fish and seafood proteomics due to the relative paucity of available protein sequence data for these animals. As can be seen in Table 22.1, this problem is surprisingly acute for species of commercial importance. To circumvent this problem, it is possible to take advantage of the available nucleotide sequences, which in many cases is more extensive than the protein sequences available, to obtain a tentative identity. How useful this method is will depend on the length and quality of the available nucleotide sequences. It is important to realize, however, that an identity obtained in this manner is less reliable than that obtained through protein sequences and should be regarded only as tentative in the absence of corroborating evidence (such as two-dimensional immunoblots, correlated activity measurements, or transcript abundance). In their work on the rainbow trout (*Oncorhynchus mykiss*) liver proteome, Martin et al. (2003b) and Vilhelmsson et al. (2004) were able to attain an identification rate of about 80% using a combination of search algorithms that included the open-access Mascot program (Perkins et al. 1999) and a licensed version of Protein Prospector MS-Fit (Clauser et al. 1999), searching against both protein databases and a database containing all salmonid nucleotide sequences. In those cases where both the protein and nucleotide databases yielded results, a 100% agreement was observed between the two methods.

A more direct, if rather more time-consuming, way of obtaining protein identities is by direct sequence comparison. Until recently, this was accomplished by *N*-terminal or internal (after proteolysis) sequencing by Edman degradation of eluted or electroblotted protein spots (Kamo and Tsugita 1999, Erdjument-Bromage et al. 1999). Today, the method of choice is tandem mass spectrometry (MS/MS). In the peptide mass fingerprinting discussed earlier, each peptide mass can potentially represent any of a large number of possible amino acid sequence combinations. The larger the mass (and longer the sequence), the higher the number of possible combinations. In MS/MS, one or several peptides are separated from the mixture and dissociated into fragments that then are subjected to a second round of MS, yielding a second layer of information. Correlating this spectrum with the candidate peptides identified in the first round narrows down the number of candidates. Furthermore, several short stretches of amino acid sequence will be obtained for each peptide, which, when combined with the peptide and fragment masses obtained, enhances the specificity of the method even further (Wilm et al. 1996, Chelius et al. 2003, Yu et al. 2003b,). MS methods in proteomics are reviewed in Yates (1998, 2004) and Yates et al. (2009).

SEAFOOD PROTEOMICS AND THEIR RELEVANCE TO PROCESSING AND QUALITY

2DE-based proteomics have found a number of applications in food science. Among early examples are such applications as characterization of bovine caseins (Zeece et al. 1989), wheat flour baking quality factors (Dougherty et al. 1990), and soybean protein bodies (Lei and Reeck 1987). In recent years, proteomic investigations on fish and seafood products, as well as in fish physiology, have gained considerable momentum, as can be seen in recent reviews (Parrington and Coward 2002, Piñeiro et al. 2003). Herein, we consider recent and future developments in fish and seafood proteomics as related to issues of concern in fish processing or other quality considerations.

EARLY DEVELOPMENT AND PROTEOMICS OF FISH

Fishes go through different developmental stages (embryo, larva, and adult) during their lifespan that coincide with changes in the morphology, physiology, and behavior of the fish (O'Connell 1981, Govoni et al. 1986, Skiftesvik 1992, Osse and van den Boogaart 1995). The morphological and physiological changes that occur during these developmental stages are characterized by differential cellular and organelle functions (Einarsdóttir et al. 2006). This is reflected in variations of global protein expression and posttranslational modifications of the proteins that may cause alterations of protein function (Campinho et al. 2006).

Proteome analysis provides valuable information on the variations that occur within the proteome of organisms. These variations may, for example, reflect a response to biological perturbations or external stimuli (Anderson and Anderson 1998, Martin et al. 2001, Martin et al. 2003b, Vilhelmsson et al. 2004) resulting in different expression of proteins, posttranslational modifications, or redistribution of specific proteins within cells (Tyers and Mann 2003). To date, few studies on fish development exist in which proteome analysis techniques have been applied. Recent studies on global protein expression during early developmental stages of zebrafish (Tay et al. 2006) and Atlantic cod (Sveinsdóttir et al. 2008) revealed that distinctive protein profiles characterize the developmental stages of these fishes even though abundant proteins are largely conserved during the experimental period. In both these studies, the identified proteins consisted mainly of proteins located in the cytosol, cytoskeleton, and nucleus. Proteome analyses in developing organisms have shown that many of the identified proteins have multiple isoforms (Paz et al. 2006), reflecting either different gene products (Guðmundsdóttir et al. 1993) or posttranslationally modified forms of these proteins (Jensen 2004). Different isoforms generated by posttranslational modifications are largely overlooked by studies based on RNA expression. This fact further indicates the importance of the proteome approach to understand cellular mechanisms underlying fish development. Studies on various proteins have shown that during fish development sequential synthesis of different isoforms appear successively (Huriaux et al. 1996, Galloway et al. 1998, Focant et al. 1999, Galloway et al. 1999, Huriaux et al. 1999, Focant et al. 2000, Huriaux et al. 2003, Focant et al. 2003, Hall et al. 2003, Galloway et al. 2006, Campinho et al. 2006, Campinho et al. 2007). In this context, developmental stage-specific muscle protein isoforms have gained a special attention (Huriaux et al. 1996, Galloway et al. 1998, Focant et al. 1999, Galloway et al. 1999, Huriaux et al. 1999, Focant et al. 2000, Focant et al. 2003, Hall et al. 2003, Huriaux et al. 2003, Galloway et al. 2006, Campinho et al. 2007).

Table 22.1. Some Commercially or Scientifically Important Fish and Seafood Species and the Availability of Protein and Nucleotide Sequence Data as of February 18, 2010, According to the NCBI TaxBrowser[a]

	Protein Sequences	Nucleotide Sequences		Protein Sequences	Nucleotide Sequences
Actinopterygii (ray-finned fishes)	257,843	1,586,862	Tetraodontiformes (puffers and filefishes)	34,032	114,496
Elopomorpha	3,218	4,459	Pufferfish (*Takifugu rubripes*)	2,593	16,406
Anguilliformes (eels and morays)	2,898	4,144	Green pufferfish (*Tetraodon nigroviridis*)	28,483	126,200

The developmental changes in the composition of muscle protein isoforms have been tracked by proteome analysis in African catfish (*Heterobranchus longifilis*) (Focant et al. 1999), common sole (*Solea solea*) (Focant et al. 2003), and dorada (*Brycon moorei*) (Huriaux et al. 2003). These studies demonstrated that the muscle shows the usual sequential synthesis of protein isoforms in the course of development. For example, in the common sole, 2DE revealed two isoforms (larval and adult) of myosin light chain 2, and likewise in dorada larval and adult isoforms of troponin I were sequentially expressed during development.

Proteomic techniques have, thus, been shown to be applicable for investigating cellular and molecular mechanisms involved in the morphological and physiological changes that occur during fish development.

The major obstacle on the use of proteomics in embryonic fish has been the high proportion of yolk proteins. These interfere with any proteomic application that intends to target the cells of the embryo proper. In a recent study on the proteome of embryonic zebrafish, the embryos were deyolked to enrich the pool of embryonic proteins and to minimize ions and lipids found in the yolk prior to two-dimensional gel analysis (Tay et al. 2006). Despite this undertaking, a large number of yolk proteins remained prominently present in the embryonic protein profiles. Link et al. (2006) published a method to efficiently remove the yolk from large batches of embryos without losing cellular proteins. The success in the removal of yolk proteins by Link et al. (2006) is probably due to dechorionation prior to the deyolking of the embryos. By dechorionation, the embryos fall out of their chorions facilitating the removal of the yolk (Huriaux et al. 1996, Westerfield 2000).

CHANGES IN THE PROTEOME OF EARLY COD LARVAE IN RESPONSE TO ENVIRONMENTAL FACTORS

The production of good quality larvae is still a challenge in marine fish hatcheries. Several environmental factors can interfere with the protein expression of larvae affecting larval quality like growth and survival rate. Proteome analysis allows us to examine the effects of environmental factors on larval global protein expression, posttranslational modifications, and redistribution of specific proteins within cells (Tyers and Mann 2003), all important information for controlling factors influencing the aptitude to continue a normal development until adult stages.

A variety of environmental factors have shown to improve the health and survival of fish larvae, including probiotic bacteria (Tinh et al. 2008) and protein hydrolysates (Cahu et al. 1999). However, the beneficial effects of these treatments on fish larvae are poorly understood at the molecular level. Only a few proteome analysis studies on fish larvae have been published (Focant et al. 2003, Tay et al. 2006, Guðmundsdóttir and Sveinsdóttir 2006, Sveinsdóttir et al. 2008, Sveinsdóttir and Guðmundsdóttir 2008, Sveinsdóttir et al. 2009), of which two have focused on the changes in the whole larval proteome after treatment with probiotic bacteria (Sveinsdóttir et al. 2009) and protein hydrolysate (Sveinsdóttir and Gudmundsdóttir 2008). These studies provide protocols for the production of high-resolution two-dimensional gels of whole larval proteome, where peptide mass mapping (MALDI-TOF MS) and peptide fragment mapping (LC-MS/MS) allowed identification of ca. 85% of the of the selected cod protein spots (Guðmundsdóttir and Sveinsdóttir 2006, Sveinsdóttir and Gudmundsdóttir 2008, Sveinsdóttir et al. 2008, Sveinsdóttir et al. 2009).

The advantages of working with whole larvae versus distinct tissues is the ease of keeping the sample handling to a minimum in order to avoid loss or modification of the proteins. Nevertheless, there are several drawbacks when working with the whole larval proteome, like the overwhelming presence of muscle and skin proteins. These proteins may mask subtle changes in proteins expressed in other tissues or systems, such as the gastrointestinal tract or the central nervous system caused by various environmental factors. The axial musculature is the largest tissue in larval fishes as it constitutes approximately 40% of their body mass (Osse and van den Boogaart 1995). This is reflected in our studies on whole cod larval proteome, where the majority

of the highly abundant proteins were identified as muscle proteins (Guðmundsdóttir and Sveinsdóttir 2006, Sveinsdóttir and Gudmundsdóttir 2008, Sveinsdóttir et al. 2008, 2009). Also, cytoskeletal proteins were prominent among the identified proteins. Removal of those proteins may increase detection of other proteins present at low concentrations. However, it may also result in a loss of other proteins, preventing identification of holistic alterations in the analyzed proteomes. Various strategies have been presented for the removal of highly abundant proteins (Ahmed et al. 2003) or enrichment of low-abundance proteins (Oda et al. 2001, Ahmed and Rice 2005).

TRACKING QUALITY CHANGES USING PROTEOMICS

A persistent problem in the seafood industry is postmortem degradation of fish muscle during chilled storage, which has deleterious effects on the fish flesh texture, yielding a tenderized muscle. This phenomenon is thought to be primarily due to autolysis of muscle proteins, but the details of this protein degradation are still somewhat in the dark. However, degradation of myofibrillar proteins by calpains and cathepsins (Ogata et al. 1998, Ladrat et al. 2000) and degradation of the extracellular matrix by the matrix metalloproteases and matrix serine proteases, capable of degrading collagens, proteoglycans, and other matrix components (Woessner 1991, Lødemel and Olsen 2003), are thought to be among the main culprits. Whatever the mechanism, it is clear that these quality changes are species dependent (Papa et al. 1996, Verrez-Bagnis et al. 1999) and, furthermore, appear to display seasonal variations (Ingólfsdóttir et al. 1998, Ladrat et al. 2000). For example, whereas desmin is degraded postmortem in sardine and turbot, no desmin degradation was observed in sea bass and brown trout (Verrez-Bagnis et al. 1999). Of further concern is the fact that several commercially important fish muscle processing techniques, such as curing, fermentation, and production of surimi and conserves occur under conditions conducive to endogenous proteolysis (Pérez-Borla et al. 2002). As with postmortem protein degradation during storage, autolysis during processing seems to be somewhat specific. Indeed, the myosin heavy chain of the Atlantic cod was shown to be significantly degraded during processing of "salt fish" (*bacalhau*) whereas actin was less affected (Thorarinsdottir et al. 2002). Problems of this kind, where differences are expected to occur in the number, molecular mass, and pI of the protein present in a tissue, are well suited to investigation using 2DE-based proteomics. It is also worth noting that protein isoforms other than proteolytic ones, whether they be encoded in structural genes or brought about by posttranslational modification, usually have different molecular weight or pI and can, therefore, be distinguished on 2DE gels. Thus, specific isoforms of myofibrillar proteins, many of which are correlated with specific textural properties in seafood products, can be observed using 2DE or other proteomic methods (Martinez et al. 1990, Piñeiro et al. 2003).

Several 2DE studies have been performed on postmortem changes in seafood flesh (Verrez-Bagnis et al. 1999, Morzel et al. 2000, Martinez et al. 2001a, Kjaersgard and Jessen 2003, 2004, Martinez and Jakobsen Friis 2004, Kjaersgard et al.

2006a, b) and have demonstrated the importance and complexity of proteolysis in seafood during storage and processing. For example, Martinez and Jakobsen Friis used a 2DE approach to demonstrate different protein composition of surimi made from prerigor versus postrigor cod (Martinez and Jakobsen Friis 2004). They found that 2DE could be used as a diagnostic tool to indicate the freshness of the raw material used for surimi production, a finding of considerable economic and public health interest. Kjaersgard and Jessen, who used 2DE to study changes in abundance of several muscle proteins during storage of the Atlantic cod (*Gadus morhua*), proposed a general model for postmortem protein degradation in fish flesh where initially calpains were activated due to the increase in calcium levels in the muscle tissue. Later, as pH decreases and ATP is depleted with the consequent onset of rigor mortis, cathepsins and the proteasome are activated sequentially (Kjaersgard and Jessen 2003).

ANTEMORTEM EFFECTS ON QUALITY AND PROCESSABILITY

Malcolm Love started his 1980 review paper on biological factors affecting fish processing (Love 1980) with a lament for the easy life of poultry processors who, he said, had the good fortune to work on a product reared from hatching under strictly controlled environmental and dietary conditions "so that plastic bundles of almost identical foodstuff for man can be lined up on the shelf of a shop." Since the time of Love's review, the advent of aquaculture has made attainable, in theory at least, just such a utopic vision. As every food processor knows, the quality of the raw material is among the most crucial variables that affect the quality of the final product. In fish processing, therefore, the animal's own individual physiological status will to a large extent dictate where quality characteristics will fall within the constraints set by the species' physical and biochemical makeup. It is well known that an organism's phenotype, including quality characteristics, is determined by environmental as well as genetic factors. Indeed, Huss noted in his review (Huss 1995) that product quality differences within the same fish species can depend on feeding and rearing conditions, differences wherein can affect postmortem biochemical processes in the product, which, in turn, affect the involution of quality characteristics in the fish product. The practice of rearing fish in aquaculture, as opposed to wild-fish catching, therefore raises the tantalizing prospect of managing quality characteristics of the fish flesh antemortem, where individual physiological characteristics, such as those governing gaping tendency, flesh softening during storage, etc., are optimized. To achieve that goal, the interplay between these physiological parameters and environmental and dietary variables needs to be understood in detail. With the ever-increasing resolving power of molecular techniques, such as proteomics, this is fast becoming feasible.

In mammals, antemortem protease activities have been shown to affect meat quality and texture (Vaneenaeme et al. 1994, Kristensen et al. 2002). For example, an antemortem upregulation of calpain activity in swine (*Sus scrofa*) will affect postmortem proteolysis and, hence, meat tenderization (Kristensen et al. 2002).

In beef (*Bos taurus*), a correlation was found between ante-mortem and postmortem activities of some proteases, but not others (Vaneenaeme et al. 1994). As discussed in the earlier section, postmortem proteolysis is a matter of considerable importance in the fish and seafood industry and any antemortem effects thereupon are surely worth investigating.

In a recent study on the feasibility of substituting fish meal in rainbow trout (*O. mykiss*) diets with protein from plant sources, 2DE-based proteomics were among the techniques used (Martin et al. 2003a, b, Vilhelmsson et al. 2004). Concomitantly, various quality characteristics of fillet and body were also measured (De Francesco et al. 2004, Parisi et al. 2004). Among the findings was that, according to a triangular sensory test using a trained panel, cooked 5-day-old trout that had been fed the plant protein diet had higher hardness, lower juiciness, and lower odor intensity than those fed the fish meal-containing diet, indicating an effect of antemortem metabolism on product texture. The study identified a number of metabolic pathways sensitive to plant protein substitution in rainbow trout feed, such as pathways involved in cellular protein degradation, fatty acid breakdown, and NADPH (nicotinamide adenine dinucleotide phosphate) metabolism (Table 22.2). In the context of this chapter,

Table 22.2. Protein Spots Affected by Dietary Plant Protein Substitution in Rainbow Trout as Judged by Two-dimensional electrophoresis and Their Identities as Determined by Trypsin Digest Mass Fingerprinting

[a]Values are mean normalized protein abundance ($\pm$ SE). Data were analyzed by the Student's *t* test ($n = 5$). In the diet designated FM, protein was provided in the form of fish meal; in diet designated PP100, protein was provided by a cocktail of plant product with an equivalent amino acid composition to fish meal.
NSH, no significant homology detected; ND, identity not determined; NA, not available.

the effects on the proteasome are particularly noteworthy. The proteasome is a multisubunit enzyme complex that catalyzes proteolysis via the ATP-dependent ubiquitin–proteasome pathway, which, in mammals, is thought to be responsible for a large fraction of cellular proteolysis (Rock et al. 1994, Craiu et al. 1997). In rainbow trout, the ubiquitin–proteasome pathway has been shown to be downregulated in response to starvation (Martin et al. 2002) and to have a role in regulating protein deposition efficiency (Dobly et al. 2004). It, therefore, seems likely that the observed difference in texture is affected by antemortem proteasome activity, although further studies are needed to verify that statement.

In addition to having a hand in controlling autolysis determinants, protein turnover is a major regulatory engine of cellular structure, function, and biochemistry. Cellular protein turnover involves at least two major systems: (1) the lysosomal system and (2) the ubiquitin–proteasome system (Hershko and Ciechanover 1986, Mortimore et al. 1989). The 20S proteasome has been found to have a role in regulating the efficiency with which rainbow trout deposit protein (Dobly et al. 2004). It seems likely that the manner in which protein deposition is regulated, particularly in muscle tissue, has profound implications for quality and processability of the fish flesh.

Protein turnover systems, such as the ubiquitin–proteasome or the lysosome systems, are suitable for rigorous investigation using proteomic methods. For example, lysosomes can be isolated and the lysosome subproteome queried to answer the question whether and to what extent lysosome composition varies among fish expected to yield flesh of different quality characteristics. Proteomic analysis on lysosomes has been successfully performed in mammalian (human) systems (Journet et al. 2000, Journet et al. 2002).

An exploitable property of proteasome-mediated protein degradation is the phenomenon of polyubiquitination, whereby proteins are targeted for destruction by the proteasome by covalent binding to multiple copies of ubiquitin (Hershko and Ciechanover 1986, Ciechanover 1994). By targeting these ubiquitin-labeled proteins, it is possible to observe the ubiquitin–proteasome "degradome," that is, which proteins are being degraded by the proteasome at a given time or under given conditions. Gygi and coworkers have developed methods to study the ubiquitin–proteasome degradome in the yeast *Saccharomyces cerevisiae* using multidimensional LC-MS/MS (Peng et al. 2003).

Some proteolysis systems, such as that of the matrix metalloproteases, may be less directly amenable to proteomic study. Activity of matrix metalloproteases is regulated via a complex network of specific proteases (Brown et al. 1993, Okumura et al. 1997, Wang and Lakatta 2002). Monitoring of the expression levels of these regulatory enzymes, and how they vary with environmental or dietary variables, may be more conveniently carried out using transcriptomic methods.

A well-known quality issue when farmed fish are compared with wild catch is that of gaping, a phenomenon caused by cleavage of myocommatal collagen cross-links that results in weakening and rupturing of connective tissue (Børresen 1992, Foegeding et al. 1996). Gaping can be a serious quality issue in the fish processing industry as, apart from the obvious visual defect, it causes difficulties in mechanical skinning and slicing of the fish (Love 1992). Weakening of collagen and, hence, gaping is facilitated by low pH. Well-fed fish, such as those reared in aquaculture, tend to yield flesh of comparatively low pH, which, thus, tends to gape (Foegeding et al. 1996, Einen et al. 1999). Gaping is, therefore, a cause for concern with aquaculture-reared fish, particularly of species with high natural gaping tendency, such as the Atlantic cod. Gaping tendency varies considerably among wild fish caught in different areas (Love et al. 1974) and, thus, it is conceivable that gaping tendency can be controlled with dietary or other environmental manipulations. Proteomics and transcriptomics, with their capacity to monitor multiple biochemical processes simultaneously, are methodologies eminently suitable to finding biochemical or metabolic markers that can be used for predicting features such as gaping tendency of different stocks reared under different dietary or environmental conditions.

SPECIES AUTHENTICATION

Food authentication is an area of increasing importance, both economically and from a public health standpoint. Taking into account the large difference in market value of different fish species and the increased prevalence of processed product on the market, it is perhaps not surprising that species authentication is fast becoming an issue of supreme commercial importance. Along with other molecular techniques, such as DNA-based species identification (Sotelo et al. 1993, Mackie et al. 1999, Martinez et al. 2001b, Pascoal et al. 2008) and nuclear magnetic resonance-based techniques for determining geographical origin (Campana and Thorrold 2001), proteomics are proving to be a powerful tool in this area, particularly for addressing questions on health status of the organism, stresses or contamination levels at place of breeding, and postmortem treatment (Martinez et al. 2003, Martinez and Jakobsen Friis 2004). Since, unlike the genome, the proteome is not a static entity, but changes between tissues and with environmental conditions, proteomics can potentially yield more information than genomic ones, possibly indicating freshness and tissue information in addition to species. Therefore, although it is likely that DNA-based methods will remain the methods of choice for species authentication in the near term, proteomic methods are likely to develop rapidly and find commercial uses within this field. In many cases, the proteomes of even closely related fish species can be easily distinguishable by eye from one another on two-dimensional gels (Fig. 22.6), indicating that diagnostic protein spots may be used to distinguish closely related species.

From early on, proteomic methods have been recognized as a potential way of fish species identification. During the 1960s, one-dimensional electrophoretic techniques were developed to identify the raw flesh of various species (Tsuyuki et al. 1966, Cowie 1968, Mackie 1969), which was soon followed by methods to identify species in processed or cooked products (Mackie 1972, Mackie and Taylor 1972). These early efforts were reviewed in 1980 (Mackie 1980, Hume and Mackie 1980).
Figure 22.6. Two-dimensional electrophoresis liver proteome maps of four salmonid fish (S. Martin and O. Vilhelmsson, unpublished). Running conditions are as in Figure 22.2. (**A**) Brown trout (*Salmo trutta*), (**B**) Arctic charr (*Salvelinus alpinus*), (**C**) rainbow trout (*Oncorhynchus mykiss*), (**D**) Atlantic salmon (*Salmo salar*).

More recently, 2DE-based methods have been developed to distinguish various closely related species, such as the gadoids or several flat fishes (Piñeiro et al. 1998, 1999, 2001). Piñeiro and coworkers have found that Cape hake (*Merluccius capensis*) and European hake (*Merluccius merluccius*) can be distinguished on two-dimensional gels from other closely related species by the presence of a particular protein spot that they identified, using nanoelectrospray ionization MS, as nucleoside diphosphate kinase (Piñeiro et al. 2001). Lopez and coworkers, studying three species of European mussels: (1) *Mytilus edulis,* (2) *Mytilus galloprovincialis*, and (3) *Mytilus trossulus*, found that *M. trossulus* could be distinguished from the other two species on foot extract two-dimensional gels by a difference in a tropomyosin spot. They found the difference to be due to a single T to D amino acid substitution (Lopez et al. 2002). Martinez and Jakobsen Friis (2004) attempted to identify not only the species present, but also their relative ratios in mixtures of several fish species and muscle types. They concluded that such a strategy would become viable once a suitable number of markers have been identified, although detection of species present in very differ-

ent ratios is problematic. Ortea et al. (2009a, b) used peptide mass fingerprinting of 2DE-separated proteins to discriminate between closely related shrimp species.

Recently, gel-free methods have received some attention. Mazzeo et al. (2008) found that specific protein biomarkers detectable with MALDI-TOF MS could discriminate among several commercially important fish species, such as those belonging to Gadidae and Pleuronectiformes.

IDENTIFICATION AND CHARACTERIZATION OF ALLERGENS

Food safety is a matter of increasing concern to food producers and should be included in any consideration of product quality. Among issues within this field that are of particular concern to the seafood producer is that of allergenic potential. Allergic reactions to seafood affect a significant part of the population: about 0.5% of young adults are allergic to shrimp (Woods et al. 2002). Seafood allergies are caused by an immunoglobulin E-mediated response to particular proteins, including structural

proteins such as tropomyosin (Lehrer et al. 2003). Proteomics provide a highly versatile toolkit to identify and characterize allergens. As yet, these have seen little use in the study of seafood allergies, although an interesting and elegant approach was reported by Yu and coworkers (Yu et al. 2003a) at National Taiwan University. These authors, studying the cause of shrimp allergy in humans, performed a 2DE on crude protein extracts from the tiger prawn, *Penaeus monodon*, blotted the two-dimensional gel onto a PVDF membrane and probed the membranes with serum from confirmed shrimp allergic patients. The allergens were then identified by MALDI-TOF MS of tryptic digests. The allergen was identified as a protein with close similarity to arginine kinase. The identity was further corroborated by cloning and sequencing the relevant cDNA. A final proof was obtained by purifying the protein, demonstrating that it had arginine kinase activity and reacted to serum IgE from shrimp allergic patients and, furthermore, induced skin reactions in sensitized shrimp allergic patients.

IMPACTS OF HIGH THROUGHPUT GENOMIC AND PROTEOMIC TECHNOLOGIES

In recent years, proteomics has moved on from technical issues related to protein separation and protein identity to highly reproducible gel-based or gel-free systems as discussed earlier. This increased ability to separate proteins and to perform peptide sequence analysis by MS has meant that the volume of data that is produced and the rate of identification of proteins is orders of magnitude greater than only a few years ago (reviewed by Seidler et al. 2010). Directly related to the increased volume of data generated means that extracting the relevant information is no longer a simple matter of discussing a list of protein identities, and interpretation of the proteins and their function is central to any medium- to large-scale proteome study (Malik et al. 2010).

The number of expressed sequence tags (ESTs) related to salmonid fish is currently in the order of 800,000 sequences, representing mRNAs encoding about 30–40,000 different proteins, other commercial species including cod, sea bass, sea bream, and catfish amongst others are quickly catching up (Martin et al. 2008). These sequences can be used to help identify amino acid sequences generated during proteomics studies, which means that now the majority of proteins can be identified rather than the minority.

There are now a considerable number of fish species whose whole genome is completely sequenced; zebrafish, two species of puffer fish, and stickleback have their genomes sequenced. And recently the sea bass, a major aquacultured species has been almost fully sequenced (Kuhl et al. 2010). The technology and tools used for these projects have led the way to expand the sequence data and interpretation of sequences from commercially important species (Forne et al. 2010)—the data that can be directly used for proteomic studies. A good example of this is zebrafish where 5716 proteins were identified with an estimated false discovery rate of 1.34% (De Souza et al. 2009).
